It does not inhibit corrosion of the iron at these points, thereby differing from zinc. Fig. 11 shows well the dissimilarity between the two metals in this respect. A plate of polished sheet iron was placed in a dilute solution of salt and water. At *A* was laid a lump of granulated tin and at *B*, a lump of granulated zinc. In the photograph may be seen the area of polished iron free from rust around the lump of zinc, whereas the tin had absolutely no effect in protecting the iron in its vicinity.

A Study of Typical Cases of Deterioration of Cast-Iron Pipe.

With these various facts in mind, an examination of certain typical cases of pipe failure may give information of value to the engineer who is called on to design works involving pipes subjected to deleterious influences.

It has already been noted that most, if not all, pipe failures occur from the influence of salt or saline waters.

A 10-in. main runs southward from Elizabeth, N. J., through the meadows to Morse's Creek. At this point, it is continued by a 6-in. line, also running southward. The general elevation of the meadow, as previously mentioned, is about 18 in. above mean high tide, and the bottom of the pipe is approximately at the level of mean high tide. There is no trolley near. Curiously enough, the 10-in. pipe, which was laid in 1893, has shown no appreciable deterioration except at a point opposite the works of the Standard Oil Company, where escaping acid waters caused corrosion. The 6-in. line, although not laid until 1902, has broken down completely. Both sizes were made by the Warren Foundry Company, and there is no apparent reason for the greater resisting power of the 10-in. line.

The salt marsh is intersected by creeks and ditches, and the surface is largely covered with fox grass. There are patches too wet for the fox grass, and these are covered with what is known as quill sage, a coarse, rank, swamp growth. It is in these patches that the chief damage to the pipe occurs. Fig. 12 illustrates the character of these meadows. The coarseness of the quill sage distinguishes the patches covered by it from those on which the finer fox grass is found.

Fig. 13 shows a photograph of a ring of the 6-in. pipe, and Fig. 14 shows a section of this pipe. In the ring, two places deeply corroded will be noticed at "B", and yet the exterior is smooth, to casual ex-

amination sound, and is neither swelled nor pitted, but retains its original sharp outline. At "A" the same thing is noticed, except that a slight crack occurs between the sound and corroded parts in one place. Just below "A", the corrosion extends nearly through the pipe. This condition exists in the section shown in Fig. 14, where the pipe has been completely penetrated. The interior is smooth and not tuberculated.

The corroded portion has the general appearance and consistency of graphite, and cuts like that substance. When first removed from the swamp, it is much softer, more like soft putty. When it is pulverized for analysis it is brown, and makes a brown streak. It is possible to write on paper with a fragment of the pipe, the marks resembling those made by a brown crayon.

If some filings of the unchanged metal are sifted on a card beneath which is placed a horse-shoe magnet, they arrange themselves in magnetic curves, as shown to the left of Fig. 15. Filings from the corroded part, on the contrary, if also sifted on a card with the magnet beneath, fall as an inert mass, which is shown on the right side of Fig. 15. From this it will be seen that, when carried to completion, the iron is completely changed from the metallic state, and that which is not leached out as chloride, remains as hydroxide.

One piece of the corroded portion contained only 42.2% of iron. Another portion had the composition given in Table 6, according to the analysis by Mr. Edward J. Pugh.

TABLE 6.—Corroded Portion of Pipe from Elizabeth.

Iron	50.62 per cent.
Silica	0.31 " "
Chlorine	0.72 " "
Manganese	0.46 " "
Silicon	22.32 " "
Combined carbon	0.63 " "
Graphitic carbon	5.51 " "

At a part not very deeply corroded, the specific gravity of a complete cross-section of the pipe was 5.18. The specific gravity of a piece from the corroded part of the pipe was only 2.2. The specific gravity of cast iron, as given by Trautwine, varies from 6.9 to 7.4, and is assumed to be 7.15.

Three microscopic views of a polished section of the uncorroded pipe are shown in Figs. 16, 17, and 18. Fig. 17 is magnified 50 diam-

FIG. 12.—SALT MEADOW, ELIZABETH, N. J., SHOWING COARSE PATCHES OF QUILL SAGE AMONG THE FINE FOX GRASS.

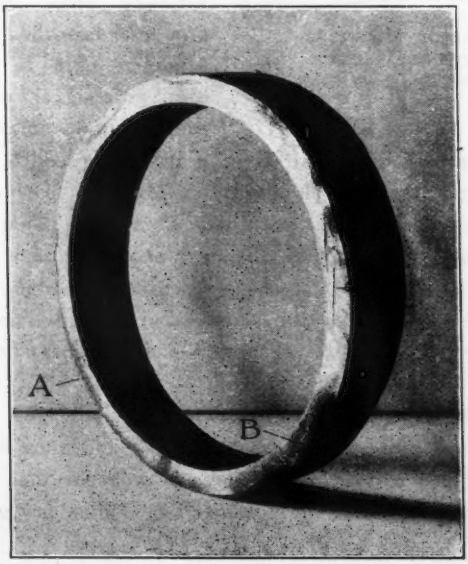

FIG. 13.—RING FROM 6-INCH CAST-IRON MAIN, ELIZABETH, N. J., SHOWING CORROSION.

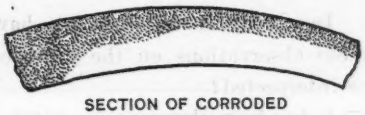
eters, Fig. 18 40 diameters, and Fig. 16, approximately, 150 diameters. The thin plates of free carbon referred to in describing the composition of cast iron can readily be seen, interspersed with the ferrite. Fig. 19 shows a micrograph of a portion of the corrosion magnified 40 diameters. Owing to the softness of the material, it is impossible to obtain a high polish on these specimens, so that the view is somewhat obscured by the shadows, but, in Fig. 20, where the carbon is indicated by heavy lines, it will be seen that the graphite plates are much thicker than they are in the unchanged metal.*

Fig. 21 shows in plan and section a piece of the pipe corroded in spots. In this, as in the other examples, the sharp original outline of the metal remains even after the metallic iron has been completely removed or oxidized. A paraffin dam was placed around this piece of pipe, and ferroxyl reagent poured on. The lower part of Fig. 21 shows the result. Where there was a deep corrosion, as at the bottom of the figure, no change took place. The iron alongside this developed two red nodes, showing the presence of hydrogen ions, and a wavy cloud of blue indicates where the iron is passing into solution. A section of pipe, similar to Fig. 14, when placed in a petri dish with ferroxyl, strongly developed the red color all along the outside or deeply corroded part, and a perfect mass of blue from all the uncorroded portion. This action is much more vigorous than that undergone by either a steel wire nail, a wrought-iron nail, or a piece of cast-iron soil pipe lying in the same petri dish. The chlorine present in the corrosion (as shown by Table 6) doubtless accounts for the vigor of the reaction observed.



SECTION OF CORRODED PIPE TAKEN FROM SALT MARSH, ELIZABETH, N.J.

FIG. 14.

At Atlantic City the behavior of the pipe was similar to that at Elizabeth. The conditions also were analagous, the chief difference being that the salt meadow was only 6 in. above mean high tide, so that the pipe was subjected to more frequent alternations of water and moist air.

Two samples of soil were collected by the writer from the Atlantic City meadows, one of them ½ in. from a corroded part of the cast-iron

* See page 1651, comments on analysis of corroded pipe at Syracuse.

main, and the other 3 ft. away. The analysis made by Mr. Edward J. Pugh, is given in Table 7.

TABLE 7.—Analysis of Soil from Atlantic City Meadows.

	Soil within ½ in. of pipe.	Soil away from pipe.
SiO_2 (insol. in HCl)	18.68	32.27
Al_2O_3, CaO, etc.	10.57	22.78

Al_2O_3 " " "	1.91	1.19
Fe_2O_3 " " "	46.57	9.11
NaCl	1.93	0.95
CaO (sol. in HCl)	0.99	0.83
MgO " " "	0.00	0.00
Sulphates	0.00	0.00
Organic acids	0.00	0.00
H_2O (at 105° cent.)	6.28	28.92
Volatile matter besides H_2O (ignition)	13.27	3.96
	100.43	100.29

In the light of what we have learned experimentally, what do these observations on the corroded pipe signify, and how shall they be interpreted?

It has been shown (page 1658) that aqueous solutions of most acids dissolve iron. If hydrochloric acid is used, ferrous chloride and hydrogen are the resultant products, the former oxidizing into ferric chloride in the presence of air. It has also been shown that, if only a trace of acid is present, the iron will be deposited from the solution as hydrated ferric oxide. It is probable* that in salt water the reaction may be represented by the equation:

$$Fe + 2NaCl + 2H_2O = FeCl_2 + 2NaOH + H_2.$$

In the presence of air or of dissolved oxygen in the water, this free hydrogen oxidizes to water, the iron in solution yields ferric hydroxide, and the process continues. The chemical analysis of the portion practically free from metallic iron contains as low as 42.2% of that element, a small part of which is in the form of chloride. Clearly, part of the iron has been removed in solution, and part remains as the hydroxide, the carbon present in the combined form being left behind, and, as shown in the microscopic sections, has thickened the plates of free carbon originally in the free iron.

* Friend, "Corrosion of Iron and Steel," p. 147.

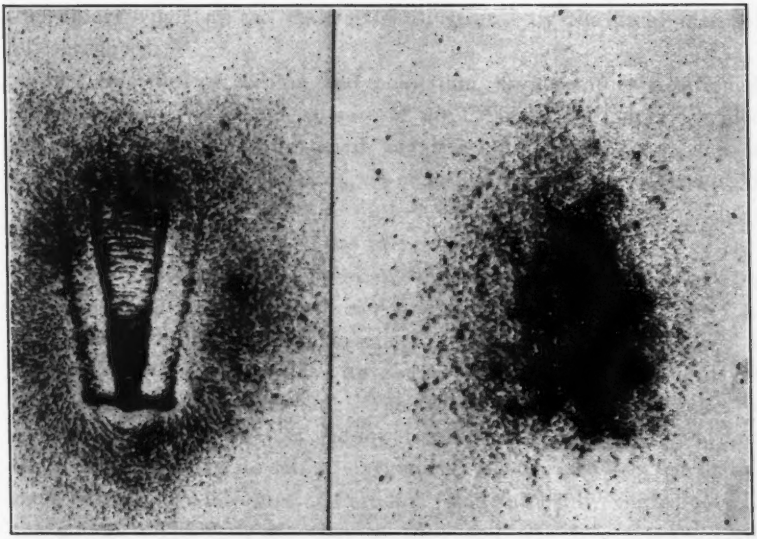

FIG. 15.—BEHAVIOR TOWARD THE MAGNET OF FILINGS FROM CORRODED AND UNCORRODED PARTS OF PIPE COMPARED.

FIG. 16.—SECTION OF CAST-IRON PIPE, ELIZABETH, N. J., MAGNIFIED 150 DIAMETERS.

The oxides of iron are electro-negative to the metal, so that electrolysis plays its part, as shown by the ferroxyl reagent, and the extraordinary vigor of the reaction is illustrated by the great mass of blue produced.

The chlorides of sodium and potassium, as heretofore mentioned, cannot corrode iron in the absence of air. Magnesium chloride, which is present in sea water in small quantities, is able to do so, but to get the full corrosive effect of sea water, plenty of air is essential.

It has been shown (Fig. 7) that the greater the surface of liquid exposed to the air, the more the corrosion is intensified.

In the salt marshes in question, the tide rises and falls, passing through a multitude of creeks and ditches all over the meadows. At Elizabeth, it ordinarily reaches about to the bottom of the pipe; at Atlantic City, it covers it. As shown in Fig. 22, this affords an ideal condition for corrosion. The liquid at high tide touches or surrounds the pipe, as in *A*; at low tide, it falls, air rushes in to take its place, and a moist, saline, oxygenated, spongy mass of earth and roots surrounds the pipe. Carbonic acid probably contributes to the action. The Atlantic City meadow soil was free from organic acids. In the sample of soil taken ½ in. from the pipe, there was 46.57% of Fe_2O_3 and even 3 ft. away, iron occurred in large quantities, there being 9.11% of Fe_2O_3. This would appear to show that it had been dissolved from the pipe as $FeCl_2$, and, after diffusing or flowing away from the pipe, as the tides rose and fell, was deposited as hydroxide.

It is further to be noted that at Elizabeth, where, on account of the elevation of the meadow, the top of the pipe was not so frequently wet as the bottom, the blow-outs generally were in the bottom of the pipe. At Perth Amboy, the top and upper sides suffered most. At Atlantic City, also, the condition of the pipe was worse at the top than at the bottom. This was to be anticipated on account of the relative elevations of the pipe and high tide. At Elizabeth, the high tide reached the bottom of the main; consequently, the top was not subjected to the saline influences so frequently. At Atlantic City, the pipes, ordinarily, were covered at high tide, and, being laid farther below the surface, air was more plentiful at the top, which, therefore, in presence of an ample quantity of salt water and with a more abundant supply of oxygen than the bottom, suffered most.

At Syracuse, the portions constantly submerged did not give out. Probably, too, the concentrated saline content in these brine-soaked lands produced an inhibiting effect, as shown in Fig. 3. The damage took place above the permanent water table, where both air and salt water were enabled to reach the pipe.

Analyses of the corroded and uncorroded portions of the Syracuse pipe were made for the Water Department by Dr. Ernest N. Pattee, of Syracuse University, and are given in Table 8.

TABLE 8.—ANALYSES OF CORRODED PIPE FROM SYRACUSE, N. Y.

	Non-corroded portion.	Corroded portion.
Silicon	0.15 per cent.	1.49 per cent.
Sulphur	0.11 " "	0.20 " "
Phosphorus	1.26 " "	1.39 " "
Manganese	0.30 " "	0.38 " "
Total carbon	3.65 " "	4.21 " "
Graphitic carbon	2.85 " "	3.84 " "

"The corrosion contained 33% of insoluble residue consisting of about 10% graphitic carbon and 22% of silicon (Si) and silica (SiO_2). Total carbon in the corrosion = 11.2%, consisting almost entirely of graphitic carbon. Sulphur in corrosion = 3.0%. Apparently, the process which accounts for the corrosion either dissolves the greater part of the combined carbon or converts it into the graphitic variety."

An analysis of the soil surrounding this pipe, made by Mr. Edward J. Pugh, disclosed that it was acid to phenol-phthalein, and contained 3.42% of organic acids. This is interesting, from its analogy to the soil conditions in Illinois, cited by Mr. Older, where steel bridges were damaged so badly by the acid soil.

On the whole, the evidence chiefly observed with cast-iron pipe would seem to indicate that organisms, whether animal or vegetable, had but little to do with the effects observed. Salt water and air seem to be the active agents, probably aided by carbonic acid, and the exclusion of either is followed by increased durability of the pipe.

The evidence given by Mr. Reimer, in which cinders caused pipe corrosion, the similar experience at Syracuse, and the German case resulting presumably from local electrolysis due to the presence of gypsum crystals, indicate the necessity for caution where pipe is likely to be subjected to such influences. Some years ago, a tunnel leading from the Susquehanna River to the power-house of the Cen-

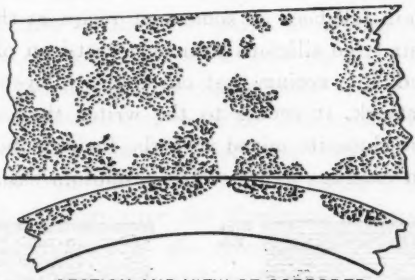
tral Pennsylvania Traction Company, at Harrisburg, was constructed under the supervision of Mason D. Pratt, M. Am. Soc. C. E. This tunnel passed through the property of the Central Iron Works, on parts of which there were large slag dumps. The water flowing into the tunnel was so sulphurous from the sulphur in the slag, that it greatly impeded the progress of the work and was most unwholesome for the workmen. Cast-iron pipe in such a location would undoubtedly undergo rapid deterioration.



SECTION AND VIEW OF CORRODED PIPE FROM ELIZABETH, N.J.

ACTION OF FERROXYL REAGENT ON SAME PORTION OF PIPE

FIG. 21.

Where low lands are filled with cinders, ordinarily, no trouble need be feared, but when subjected to periodical wetting and aeration, some precautions are desirable.

Acid mine waters are also very corrosive, and should be guarded against, when pipe is subject to their action. In the mines themselves this would generally be economically impracticable, but, in municipal works in the vicinity, where the pipe may be attacked, preventive means should be resorted to.

PREVENTION OF EXTERNAL CORROSION.

A recipe to prevent rusting of iron, given in an old work called "The Laboratory", published in London, in 1790, is as follows:

"Fry a middling eel in an iron pan, and when brown and thoroughly fryed, express its oil, and put into a phial, to settle and become clear in the sun. Iron work, anointed with this oil, will never rust, although it lay in a damp place."

The actions of iron under the complex conditions obtaining in Nature are so various, and the observed results so often discordant, that one would fain fall back on some such recipe as this as a cure-all.

Bearing in mind the silicious skin of a cast-iron pipe and its protective effect, and also noting that chromium alloys of iron are resistant to acid attack, it occurs to the writer that some chromium compound such as chromite mixed with the facing sand of the moulds might produce in castings a protective chromium skin.

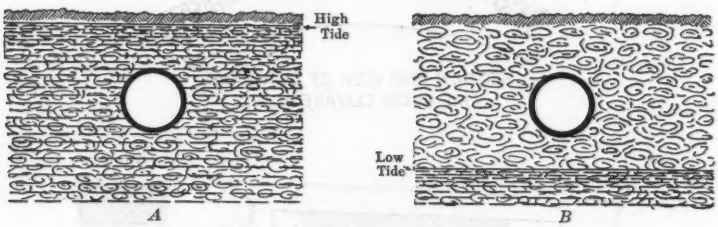


DIAGRAM SHOWING AERATION EFFECTED IN A TIDAL MARSH
A—HIGH TIDE B—LOW TIDE

FIG. 22.

It is a subject wherein an apparently well-reasoned argument may be completely upset. For example, as zinc in water, either fresh or salt, protects iron and is itself attacked, so if iron and copper are immersed in a liquid capable of acting on each, and are connected by a conductor, a current will pass from the copper to the iron, and the iron will be dissolved. And yet, after a series of exhaustive experiments, Mr. Richard H. Gaines* states:

"The legitimate conclusion from the foregoing experiments is that rather less than more galvanic action arises from contact between steel and the other metals of the series than from contact between steel and steel. In actual practice it has been found that if a steel nut is put on a steel bolt and subjected to corrosive conditions, in a comparatively short time the steel nut will have to be hammered or

* *Engineering Record*, Vol. LXIX, p. 104.

split off, if gotten off at all, on account of rusting together from local corrosive action; whereas a brass or bronze nut on a steel bolt under similar condition can be readily screwed off."

Mr. H. J. Force* is authority for the statement that cast iron used in pumping machinery by the Delaware, Lackawanna and Western Railroad Company, was badly corroded by acid mine waters. As bronze bushings, valves, and impeller blades were used, it was thought that the action was due to galvanic action from contact of the two metals in the acid water. On substituting cast iron for the bronze valves and bushings, so that the parts in contact would be of the same metal, the corrosion increased, and the cast iron deteriorated even more rapidly than when in contact with bronze.

As far back as the days of the elder Pliny, who was killed in the same eruption of Vesuvius that destroyed Pompeii in A. D. 79, this effect of iron on iron was noted. Pliny states that Alexander the Great, to repair a bridge over the Euphrates, "sometime bound and strengthened the bridge over the river there; the links whereof, as many as have been repaired and made new since, do gather rust, whereas the rest of the first making be all free therefrom." Modern experience has shown that if the old and new iron are of absolutely similar metal, one will be as durable as the other; but that if they are of a slightly different composition, it is not necessarily either the inferior or the newest metal which suffers most, that depending on the electrical phenomena resulting.

It is unsafe to reason too positively from results obtained with liquid electrolytes as to what will happen to iron buried in soils. Moreover, time is such an important factor that conclusions drawn from accelerated tests may be most misleading. At the beginning of this paper, reference was made to the conclusions of Messrs. McCollum and Logan.†

"The relatively high rate of self-corrosion of cast iron as compared to the other kinds of iron tested is contrary to the generally accepted idea that cast iron is more resistant to self-corrosion than wrought iron. It is not improbable that this impression in regard to the superiority of cast iron has grown out of the fact that cast iron structures are usually made relatively heavy and they also tend to corrode more uniformly than wrought iron or steel, both of which factors would tend greatly to increase the life of the former."

* *Engineering Record*, Vol. LXIX, p. 104.

† "Electrolytic Corrosion of Iron in Soils," p. 32.

The writer cannot subscribe to this view. The ordinarily accepted idea of the superior durability of cast iron arises, in his opinion, from the fact that cast iron, generally speaking, is more durable than other commercial forms of wrought iron and steel.

One explanation of this discrepancy may be furnished by the experiments of K. Arndt,* who determined the extent of corrosion in iron and steel by the oxygen absorbed by the metal in rusting. Fig. 23 shows the result of these experiments.

The cast iron at first corrodes as rapidly as the mild steel, and more than twice as fast as the weldless tube. At the end of 43 days, however, the mild steel had undergone twice as much oxidation as the cast iron, and the weldless tube four times as much.

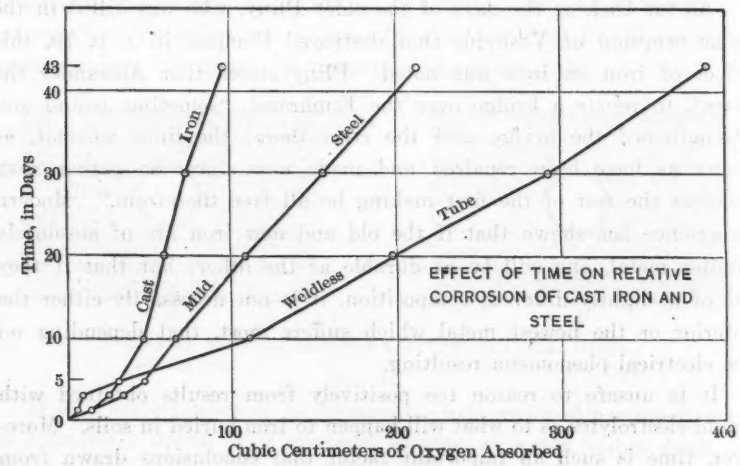

FIG. 23.

It would seem, therefore, that even in the corrosive zones, in which deterioration of the cast-iron pipe has been greatest, the remedy is not to be sought by the substitution of wrought iron or steel, but rather by the improvement, if possible, of the skin resistance of the metal. Where, for any reason, such as with flanged pipe, bolts and nuts are necessary, bronze need not be feared on account of its supposed galvanic effect on the iron.

A second method of protecting the pipe, based on the well-known rust-inhibiting properties of the chromates and certain other substances, whereby the iron is rendered "passive", does not seem prac-

* *Chemiker Zeitung*, 1910, Vol. XXXIV, p 425.

ticable, in that a sufficient quantity of such material to protect the iron indefinitely could scarcely be added to the soil surrounding the buried pipe at a reasonable cost. Therefore, this interesting phase of the subject has not been taken up in this paper. A temporary passivity would be of no practical importance.

The use of lime in the trenches, so as to encase the pipe in an inhibiting alkali, ought to be of service, and is worth trying. Encasing in concrete would be expensive, but would protect the pipe, if properly done.*

Another method, suggested at Perth Amboy, is to leave the pipe in open trench. This might help materially, as the alternate wetting and drying would probably be less destructive than the constant exposure to moist air, salt, and carbonic acid in the swamp or meadow soil. At Atlantic City this principle has been carried one step farther, and the new 48-in., cast-iron, water main across the salt marsh has been raised above the surface of the meadow, so as to be entirely in the air.

As will be seen by Fig. 24, it is supported on reinforced concrete bolsters, 5 ft. 2 in. long, 20 in. thick, and about 5 ft. 6 in. high, so that the bottom of the pipe is about 1 ft. above the meadow. Each bolster, in turn, is carried on two piles of an average length of 37 ft., driven by a 2 000-lb. hammer, the final penetration required being not more than 1 in. under five strokes of the hammer falling 14 ft. The bolsters are 6 ft. from center to center. Between the pipe and the bolster there is a piece of hard vulcanized fiber, $\frac{3}{8}$ in. thick. On the pipe laid in summer, expansion was provided for by allowing a minimum space of $\frac{1}{4}$ in. between the shoulder and spigot end of each pipe. In addition, a sleeve is inserted once in each 2 000 lin. ft. of pipe. The entire design has been carefully studied and worked out by Mr. Lincoln Van Gilder,† Chief Engineer, and T. Chalkley Hatton, M. Am. Soc. C. E., Consulting Engineer of the Water Department. Several thousand feet of the main are already completed. It would seem to solve the problem, either in a warm climate or where the main is large enough to be exposed without danger of freezing; and where it is permissible to have the pipe above the surface.

* For use of cement as a wash, see Franklin Riffle, M. Am. Soc. C. E., Discussion on "The Preservation of Materials of Construction," *Transactions*, Am. Soc. C. E., Vol. L, p. 313 *et seq.* See also Discussion on "Relative Permanency of Steel and Masonry Construction," *Transactions*, Am. Soc. C. E., Vol. XLIX, p. 74, for many interesting data.

† Who furnished this information to the writer. See also *Engineering News*, Vol. LXX, p. 1046.

At Elizabeth an analogous, though less elaborate, expedient has been adopted. A 6-in. pipe could not be raised above the meadow and left exposed without danger of freezing, so it was laid on the surface, covered with a mound of meadow soil or mud some 6 in. thick, and the mound was then sodded with fox grass. This was done in the spring, so that the sod would make vigorous growth and protect the embankment. Although this gives great promise of obviating the trouble, it has not been in place long enough to predict its success with absolute certainty.

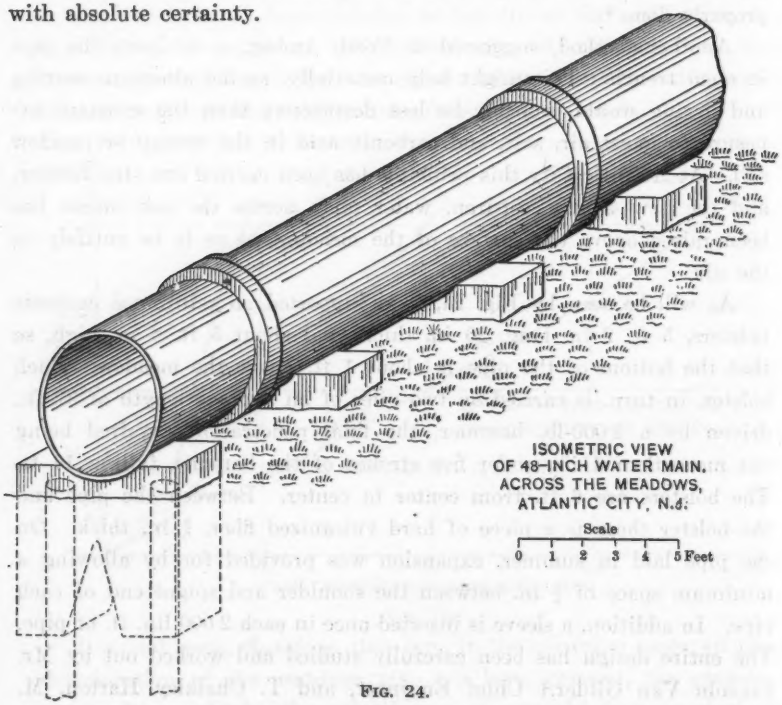

FIG. 24.

Very frequently, conditions are met which prohibit such a solution of the problem. At Syracuse, for example, where the mains are laid in the streets, such a mode of construction is not to be thought of.

Bearing in mind the protective effect of zinc, as shown in Fig. 11, it might at times be desirable to galvanize the cast iron in such locations, instead of giving it the ordinary bituminous coating. The United States Government has utilized galvanizing in some instances for the protection of gratings, covers, and similar castings, but as far as

the writer is aware, it has never been applied to cast-iron pipe. Double galvanizing, as it is called, should be used in such cases. This is a trade term, which does not mean that the iron has been dipped twice, but merely that it carries a much heavier coating than the ordinary galvanized metal. The heavy coating is not suitable for articles which may be subjected to bending, as it will crack off, but this objection does not apply to a rigid article like cast-iron pipe.

Conclusions.

First.—Under ordinary conditions of soil, cast-iron pipe has a probable life of from one to three centuries, as far as external corrosion is concerned.

Second.—Under certain soil conditions, such as salt marshes or saline soils, cast-iron pipe may be rendered useless in from 7 to 20 years.

Third.—At times, cinder and slag fills may exert a strongly deleterious influence. Acid mine waters are also destructive.

Fourth.—Substituting wrought-iron or steel pipe for cast iron is ineffectual. Cast iron will outlast the others.

Fifth.—Remedies fall under four heads:

A.—Increasing the skin resistance of cast iron;

B.—Utilizing the protective influence of alkalis by surrounding the pipe with lime or cement, where such is practicable;

C.—Exclusion of acids, salt, or air;

D.—Galvanizing the cast-iron pipe, thus protecting it at the expense of the zinc.

Sixth.—So many opposing factors are at work simultaneously, that great caution is necessary in reasoning from effect to cause and in suggesting remedies based on observed fact. It is the unexpected that frequently happens.

Acknowledgments.—The writer is under great obligations to the persons who have aided him with information, and to the published articles bearing on the subject. The references in the text will indicate to whom credit is due for this assistance, and to these gentlemen he wishes to express his thanks.

Doubtless much that is pertinent to the subject has not been mentioned, but it is hoped that any such facts may be brought out in the discussion.

THE STEREOSCOPIC METHOD OF SURVEYING, AND A FIRST TRIAL OF ITS APPLICATION TO A RAILWAY SURVEY IN CHINA.*

By Georg A. G. Müller, Esq.†

Synopsis.

In order to demonstrate the advantages of the stereo-photographic method of surveying, the writer made a survey for a part of the proposed Hankow-Ichang Railway, through a difficult piece of country in the very rough and tortuous valley of the Yangtze Kiang River, in China. The instruments and methods used are described and illustrated in detail by their application to this survey.

The photo-theodolite is a combination of a metallic box camera and a theodolite; the optical bases are measured with a rod, mounted on a tripod; the three co-ordinates of each point on the negatives (or diapositives) are measured on the stereo-comparator, which, perhaps, is as important an instrument as the photo-theodolite in stereo-photographic work; the points are plotted on a special drawing device consisting of a glass plate to which steel rulers are pivoted and clamped. The other apparatus consists of double plate-holders, photographic plates, etc., etc.

* This paper will not be presented at any meeting of the Society, but written communications on the subject are invited for subsequent publication in *Proceedings*, and with the paper in *Transactions*.

† Regierungs Baumeister; Dipl. Ing. (Berlin); Professor of Civil Engineering to the Government University, Peking, China.

The general plan of the survey included a preliminary reconnaissance of the territory, a triangulation network with a base line in the open part of the valley, and a line of levels in the bottom of the valley establishing bench-marks from which the elevations of the photo-theodolite could be determined or checked. The photographic stations or standpoints were then selected, and from these the photographs were taken, either at the time or whenever the weather and the position of the sun were favorable.

On account of the newness and possible importance of stereophotographic surveying, the theory is illustrated and described in considerable detail, and also the manner in which the points on the photographs are measured and plotted.

It is claimed for this method that it is simple, about seven times as rapid as a tacheometrical survey, is not expensive, and is especially suitable for work in rough and difficult territory.

Although the paper relates only to the application of this method to a preliminary railway survey, it may be used for other purposes, for instance, stereographic pictures, taken from a fixed base line, will serve to record the progress of work, as they will enable one to check quantities of earthwork, masonry masses, dimensions, the agreement of structure with design, etc., and may be examined at headquarters at any time.

While making a topographic survey in Hanyang-Wuchang during the summer of 1913, with his students, the writer had an opportunity to demonstrate the stereo-photographic method of surveying to Councillor Linow, Chief Engineer of the Hankow-Ichang Railway. The particular advantages and the results obtained recently in Europe by this method convinced the Chief Engineer that it might be advantageous to make a trial of it in China, and the writer was commissioned to make a preliminary photographic survey of the most difficult part of the proposed line during the summer vacation.

The party consisted of the writer as Chief Engineer, and later two German engineers, six of his former students, now graduated, ten Hupeh students, graduated in Japan, and a few draftsmen.

The preliminary line, proposed after the first reconnaissance, runs for about 20 li* (7 miles) nearly parallel to the Yangtze Kiang,

* 1 li = about ⅓ mile.

thence for 20 to 30 li (7 to 10 miles) through hilly, rolling country, and, finally, after crossing a tributary of the Yangtze, reaches the district under discussion. The valley is extremely rough and tortuous, and, with its steep rocky bluffs and wooded slopes, presents great difficulties to the locating engineer, so that the work served as a valuable test of the possibilities of this method of surveying.

This valley, measuring 10 to 12 li (3.6 to 4.3 miles) on the line and about 17 li (6.1 miles) along the river, represents the *pièce de résistance* of the Hankow-Ichang Line. Probably it will be the most expensive part, on account of the many structures required. For this reason the survey was first commenced on the scale of 1:2 500; the rolling country was to be surveyed later.

General Plan of the Work.

The line of the reconnaissance was marked by flags on high bamboo poles every 400 to 600 m. (1 300 to 2 000 ft.). Then a triangulation net was made over the whole district to be surveyed, starting from a favorably located base line in the broad open part of the valley. It was endeavored to include in this triangulation as many points on the line as possible, and, in order to avoid confusion, such points were indicated by poles with flags at their tops; the poles at the triangulation points also bore flags in the middle. Each flag carried a wooden target at a height of about 1½ m. from the ground. Altogether, about 30 points were established.

A base line of about 214 m. (700 ft.) was carefully measured with 5-m. wooden measuring rods which had been standardized in Peking. From each point the direction of all visible points was determined within 10″ with four readings. At the same time, most of the elevation angles were taken.

The triangulation served a double purpose: First, it made possible the orientation of the standpoints of the photo-theodolite. Secondly, its points (the elevations of which were determined trigonometrically), formed an important control for the photographic plates.

As explained later, this check served, even when the bamboo poles did not appear on the plates. The targets answered as base points for the stations, as the lower parts of the poles were frequently concealed by grass or otherwise, the average height of the theodolite above the ground being 1½ m.

The "distances" of the triangulation (400 to 1 200 m.) (about 1 300 to 4 000 ft.) were calculated and plotted, and precise levels were run along the bottom of the valley. From these the elevations of the photo-theodolite were determined or checked.

The selection of the photographic standpoints was made, the directions and base lines for the stereographic exposures were taken, base lines were measured and oriented with reference to the triangulation, and occasionally a few elevation angles were measured by the photo-theodolite. The points for the camera were marked by pegs, and the photographs were taken, if the weather and position of the sun permitted, or postponed until a more favorable time. The plates were developed and diapositives and prints were made at headquarters.

The next stage of work was the taking of measurements from the plates in the stereo-comparator. This is a most important instrument and on it the progress of the survey depended. It was kept continuously at work during daylight, by shifts of operators, throughout the whole survey.

The determined co-ordinates from each pair of plates were plotted on tracing paper pasted on especially arranged glass plates, and the orienting directions were laid out. Then these sheets (one for each pair of photographic plates, Figs. 18 and 19) were laid on the triangulation map and oriented so that the orienting lines would pass through the triangulation points; the other points were then transferred by pricking, and the elevations indicated.

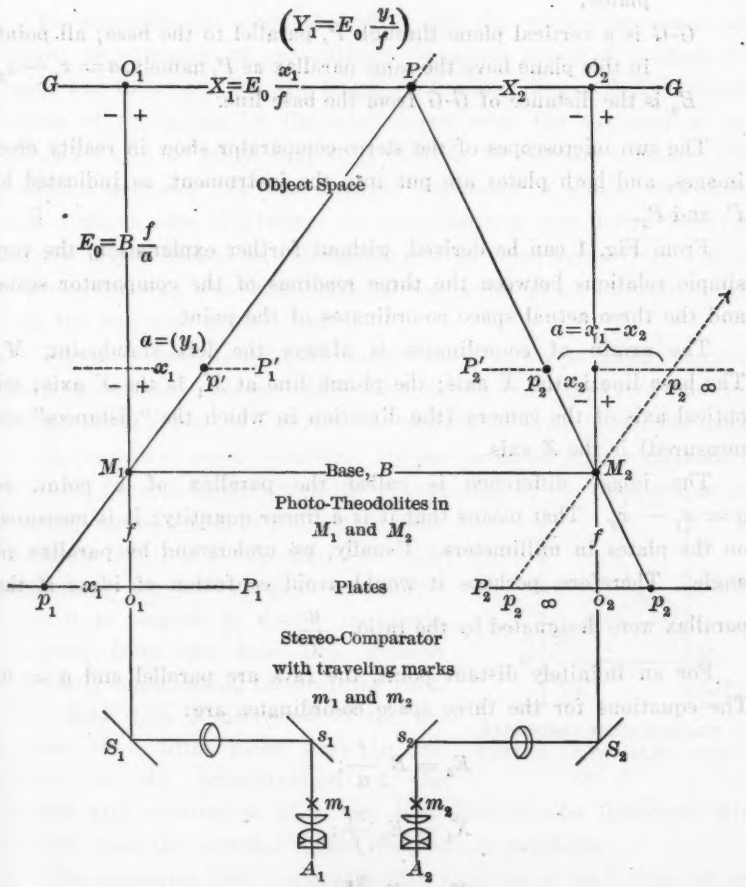
Having transferred several consecutive "point sheets," the drawing in of contour lines was commenced. Finally, the map was taken into the field for comparison with the actual topography, and objects which had been concealed from the camera, or had otherwise been missed, were filled in by free hand or by stadia, according to their size and importance. Also, on this last visit to the field, the topographic signs (buildings, culture, etc.), were indicated on the map.

Then the paper location was made on the original map or on tracings from it.

Theory of the Stereo-Photogram.

The theory of a stereo-photo-grammetrical exposure, in which both plates are in the same vertical plane, is illustrated by Fig. 1, in which M_1 and M_2 denote standpoints of the camera, that is, the center

of the objective. The difference of a few centimeters between center of objective and center of instrument can be neglected.



THEORY OF A NORMAL STEREO-PHOTO-GRAMMETRICAL EXPOSURE

FIG. 1.

M_1-M_2 (= B) is the horizontal projection of the base line;
M_1-O_1 and M_2-O_2 are the optical axes, and are parallel to one another and perpendicular to the plates and to the base line;
f is the focus of the objective;

P is any point to be determined;

p_1 and p_2 are the image points of P on P_1 and P_2, the negative plates;

G-G is a vertical plane through P, parallel to the base; all points in this plane have the same parallax as P, namely, $a = x_1 - x_2$;

E_0 is the distance of G-G from the base line.

The two microscopes of the stereo-comparator show in reality erect images, and both plates are put into the instrument, as indicated by P_1 and P_2.

From Fig. 1 can be derived, without further explanation, the very simple relations between the three readings of the comparator scales and the three actual space co-ordinates of the point.

The origin of co-ordinates is always the left standpoint, M_1. The base line is the X axis; the plumb line at M_1 is the Y axis; the optical axis of the camera (the direction in which the "distances" are measured) is the Z axis.

The image difference is called the parallax of a point, as $a = x_1 - x_2$. That means that it is a linear quantity; it is measured on the plates in millimeters. Usually, we understand by parallax an angle. Therefore, perhaps it would avoid confusion of ideas if the parallax were designated by the ratio, $\frac{a}{f}$.

For an infinitely distant point, the rays are parallel and $a = 0$. The equations for the three space co-ordinates are:

$$E_0 = B \frac{f}{a};$$

$$X_1 = E_0 \frac{x_1}{f};$$

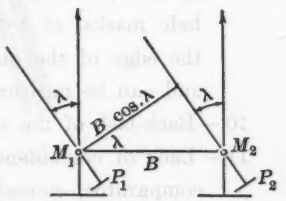
$$Y_1 = E_0 \frac{y_1}{f}.$$

It is essential in normal photo-grammetry that the two plates be in the same vertical plane. However, points can be determined from two plates not in the same plane, but, it might be mentioned, parenthetically, that in any case, with the instruments herein mentioned, a base line is used which is only from one-twentieth to one-tenth of the length of that required by the old photographic method.

The two plates are used in conjunction to determine the distance of a point, and the left-hand plate alone serves to determine its direction and elevation.

In principle, the photo-theodolite and the stereo-comparator are simply an extension of our ordinary binocular power of judging distance and direction; but the length of the base line and the magnification of the image by the microscopes raise the efficiency of our natural vision so much that it is possible to measure distance with sufficient accuracy for map-making. Although a single view gives only such an idea of distance as our experience can derive from the relative apparent size of objects, the second view, taken from a point removed laterally somewhat from the first, gives us an accurate insight into the structure of the view.

The most used, because the most simple, is the so-called "normal" stereo-photogram. Nevertheless, the scientific collaborator of the Zeiss Werkstätten, Jena, Dr. Pulfrich, has thoroughly investigated the theory of the curves of equal parallax. He has invented simple methods of plotting for exposures, where the optical axes of the photographs are equally turned either to the left or right (usually 30°), Fig. 2; therefore such exposures are of increased usefulness, and it is possible to double the angle covered from one base line without seriously complicating the drafting work. The field work is decreased at the expense of a little more work in the office, as the determination of the length and orientation of a new base line can be dispensed with. In this case, the curves of equal parallax are parabolas.



EXPOSURES WITH EQUALLY TURNED, OR PARALLEL, AXES

FIG. 2.

The exposures with horizontal axes inclined to each other at any angle, that is, convergent, if both axes are directed to one point in the foreground, is very similar to the old method of plane-table photogrammetry. This method, however, is seldom used, owing to the difficulties of plotting, which are not yet overcome. The curves of equal parallax are ellipses. The construction of one point requires too many auxiliary lines. It would go too far afield to enter here into a discussion of the accuracy of stereoscopic vision with our

two eyes, on the ground of recent physiological investigations. Also, the writer has not the space here to derive a complete theory as to the errors in measuring with the stereo-comparator; it may suffice to mention, among other various sources of error, the following:

1.—Inaccurate determination of the base line in the field;
2.—Inaccurate determination of the focus of the objective by the makers (all views are made with a fixed-focus camera);
3.—The lens not perfectly free from optical distortion;
4.—Too coarse-grained emulsion on the plates (which must be especially prepared);
5.—Not exactly vertical position of the plates during exposure;
6.—A slight inclination of the plates in relation to each other;
7.—A slight inclination of the axes in relation to the base line, though they are still parallel to one another;
8.—Not perfectly plane plates (especially with long-focus lenses);
9.—Expansion and contraction of the plates by change of temperature; or a creeping of the gelatine film, for a like reason, or by moisture. (A check against the latter is provided by two hole marks, at a fixed distance apart, which are printed on the edge of the plate automatically at the time of exposure, and can be measured later under the stereo-comparator.)
10.—Back-lash of the screws of the comparator;
11.—Lack of coincidence of the planes of the two pictures in the comparator, caused, for instance, by difference in thickness of the glass plates;
12.—One or both of the plates not resting exactly in a horizontal position in the comparator.

Obviously, it is necessary for the surveyor to understand and take into account how much each of these sources may affect the accuracy of the result. It is necessary and possible to be able by checks to determine the sources of errors and make proper adjustments accordingly.

Instruments.

The stereoscopic method is very sensitive, and the instruments used must be of very great precision. The only manufactory of these instruments is the well-known Zeiss Werkstätten, Jena. The instruments

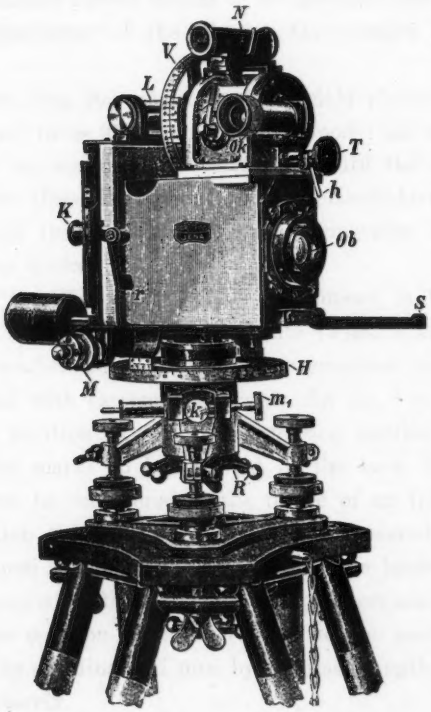


FIG. 3.—FIELD PHOTO-THEODOLITE.

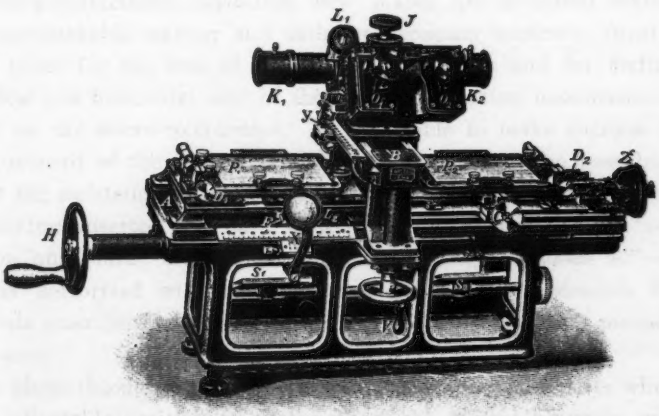

FIG. 4.—STEREO-COMPARATOR BY DR. PULFRICH.

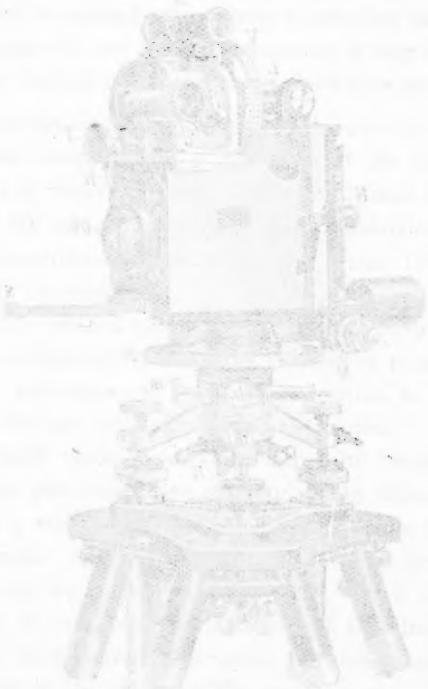


used in this particular survey belong to the geodetic outfit of the Civil Engineering Department of the Chinese Government University at Peking.

The equipment, Fig. 20, consisted of one field photo-theodolite, for 9 by 12-cm. plates, focus 98.54 mm.; three tripods; one measuring rod for optical base measurement in connection with the directing telescope of the photo-theodolite; twenty double plate-holders; one stereoscopic range-finder (power $4x$); one stereo-comparator, Model D; and a special drawing device.

The Field Photo-Theodolite.—This instrument is a combination of a metallic box camera with a theodolite (Figs. 3 and 5), so that the particular conditions of a "normal" stereogram can be fulfilled expeditiously and with extreme accuracy. An error of from 1′ to 2′ in the relative position of the plates to one another is much too great. Then the marks to be adopted in the back frame in front of the plate must be considered as the image of an infinitely distant point, from which the parallaxes are to be measured, for instance, exactly to 0.01 mm., if known fixed points in the landscape are to be dispensed with and corrections avoided. The highest admissible angular deviations in the position of the two plates to one another, therefore, are determined by dividing 0.01 mm. by the focal length, $f = 180$ mm., or 10″, approximately.

Instead of the vertical hairs previously used in the camera frame for photo-grammetrical exposures, new marks are produced which, in an unmistakable manner and with the necessary accuracy, furnish a fixed point for the zero of the values of parallax and for finding the optical and horizontal axes of the plate when taking measurements from it on the stereo-comparator. It is possible to make changes in the adjustment of the camera to the horizontal and to the base line, without the assistance of the marks in the camera frame, at any time after having inserted the dark slide. The adjustment of the two plates in one plane—to be done with an accuracy of about 10″—is not only performed with ease and precision, but is accessible for immediate examination and rectification, right up to the very moment of exposure.

The photo-theodolite proper consists of three principal parts which are in adjustable position to one another: the central bearings, with

the horizontal circle, insertable in the tripod, the camera firmly fixed to the axis of rotation, and the pointing telescope with the vertical circle.

The horizontal and vertical circles are divided into half degrees, the vernier permitting readings of 1′ and estimations of ½′. The horizontal circle is adjustable—coarse by hand and fine by micrometer screw—for the purpose of setting on a certain zero point.

The vertical axis of rotation can be firmly clamped and fine adjustment effected with a micrometer screw, which is also designed for the measurement of the base.

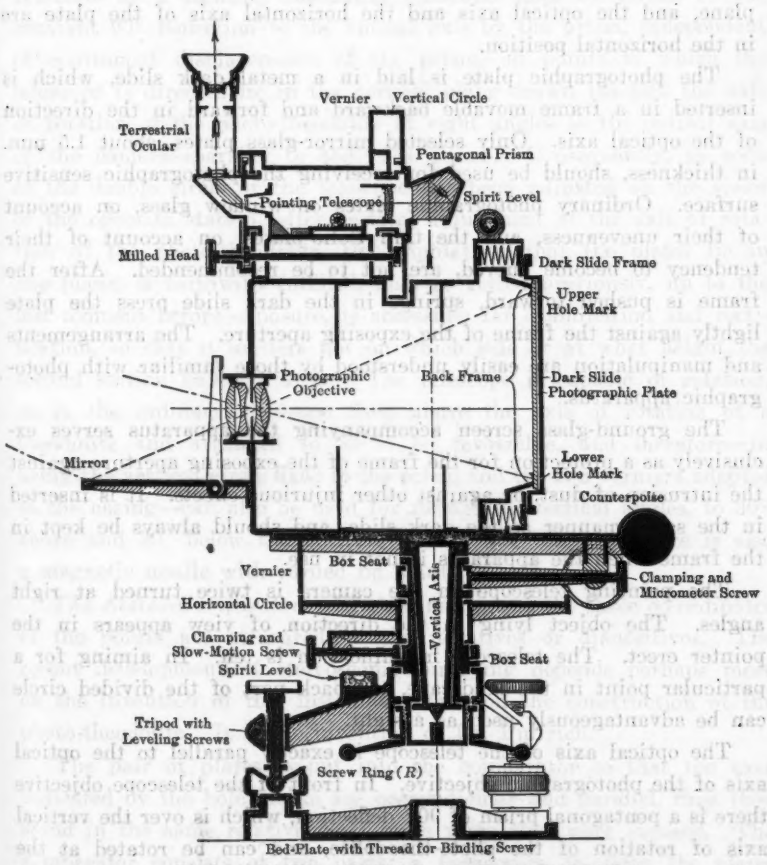
The camera casing is of light metal, cast in one piece, into which the objective is fixed in front; the back frame for the sensitive plate is behind. The optical axis is at right angles to the plane of the back frame at a certain point mentioned later.

The ortho-protar objective in the photo-theodolite is particularly suitable for photo-grammetrical and stereo-photo-grammetrical exposures, on account of its simple structure and consequently its ability to resist external physical influences, its fine definition from the center to the margin of the plate, and its well-nigh perfect orthoscopy —the deviations are demonstrably smaller than 0.01 to 0.02 mm. The horizontal image angle is more than 60°, so that in wide-angle views only six exposures—in which the margins somewhat overlap one another—are necessary for the whole circuit. The immovable objective is below the middle of the exposing aperture of the back frame. In cases where only one photo-theodolite is used, the objective is provided with a fixed stop of $\frac{f}{40}$. The focal length of the objective is most carefully determined in the works, up to 0.1 mm. for each instrument, and stated on delivery of the apparatus.

The back frame is ground perfectly plane, and adjusted so that all around the photographic plate a few millimeters are blocked out. It is exactly parallel to the axis of rotation of the photo-theodolite.

The new marks in the back frame are to be seen on the photographs, Figs. 18 and 19. They consist of two circular holes, with conical embrasures, turned toward the objective, about 0.15 mm. in diameter, one of which is in the middle of the upper margin of the frame, the other in the middle of the lower margin. The line joining the two holes is directed parallel to the axis of rotation of the photo-theodolite, and cuts the optical axis in one point.

The hole marks have this advantage, over the knife-edges generally used, that their centers undergo no displacement whatever through differences in illumination, and can be easily rediscovered under the microscope of the stereo-comparator with the necessary accuracy.



DIAGRAMMATIC VERTICAL SECTION THROUGH THE PHOTO-THEODOLITE

(Pointing telescope is drawn with the ocular in the vertical position)

FIG. 5.

Because of the adjustment mentioned, the vertical axis of rotation of the photo-theodolite, the optical axis of the camera, and the horizontal of the plate—the last is determined by the reading on the y-scale and by the slide rests of the stereo-comparator lying at right

angles to one another—form a fixed rectangular co-ordinate system. There is required then only the exact vertical setting of the axis of rotation, which is done with the set-screws on the tripod and the 10-in. spirit level on the camera, and then the plate lies in the vertical plane, and the optical axis and the horizontal axis of the plate are in the horizontal position.

The photographic plate is laid in a metal dark slide, which is inserted in a frame movable backward and forward in the direction of the optical axis. Only selected mirror-glass plates, about 1.5 mm. in thickness, should be used for receiving the photographic sensitive surface. Ordinary photographic plates on window glass, on account of their unevenness, and the thin Solio-plates, on account of their tendency to become curved, are not to be recommended. After the frame is pushed forward, springs in the dark slide press the plate lightly against the frame of the exposing aperture. The arrangements and manipulation are easily understood by those familiar with photographic apparatus.

The ground-glass screen accompanying the apparatus serves exclusively as a protection for the frame of the exposing aperture against the intrusion of dust, or against other injurious effects. It is inserted in the same manner as the dark slide, and should always be kept in the frame when the apparatus is not in use.

The pointing telescope on the camera is twice turned at right angles. The object lying in the direction of view appears in the pointer erect. The telescope magnification is ten. In aiming for a particular point in the landscape, the back part of the divided circle can be advantageously used as a sight.

The optical axis of the telescope is exactly parallel to the optical axis of the photographic objective. In front of the telescope objective there is a pentagonal prism of 90° deflection, which is over the vertical axis of rotation of the photo-theodolite, and can be rotated at the same time as the twice-turned terrestrial ocular about the optical axis of the telescope. The telescope objective and the cross-lines take no part in the rotation. These stand in connection with the pentagonal prism and the ocular only through the roof of the camera chamber, and form a perfectly closed-in pointer telescope, secured against lateral displacements by screws and pins and against external influences by the hollow body carrying the prism and ocular. With

the assistance of this pointer, the direction of the optical axis of the photographic objective can at any moment be fixed.

In consequence of these arrangements, the pointer is simultaneously available as a sighting theodolite telescope, and, by virtue of the constant 90° deflection to the optical axis by the prism, independent of contingent displacements of the prism, all points to which the telescope is directed lie in the vertical plane drawn through the axis of rotation of the photo-theodolite at right angles to the optical axis of the camera—parallel to the back frame. Consequently, as soon as the double circle of the telescope has been adjusted on the visier of the opposite station, after vertical adjustment of the axis of rotation of the photo-theodolite, the stipulation, that the plates lie in one plane, is forthwith fulfilled, and, as stated previously, up to the last moment before exposure, is accessible for examination and rectification, so that it matters not on which side or at what height the second station happens to be. The telescope is capable of rotation, as in the ordinary telescope fixed above the axis of rotation of a theodolite and arranged so as to be revolvable, and therefore—in using the vertical circle fixed to the prism and the two verniers adapted to the casing—can also be used for measuring vertical angles, to 30° above and 30° below the horizon. Above the telescope there is also a magnetic needle with turned up point.

The Stereo-Comparator.—By this instrument the three co-ordinates of the points are measured on the negatives or diapositives. The recent development of stereoscopic surveying depends perhaps more on the invention of this instrument than on the construction of the photo-theodolite. It is the invention of Dr. Pulfrich.

The pair of plates is put into the comparator so that the axes indicated by the hole marks are perpendicular and parallel, thus they stand in the same relative position as when they were exposed. The comparator consists of two parts; a framework to carry the plates and a binocular microscope for viewing them.

In detail, the construction of this instrument, Fig. 4, is as follows: A heavy bed, A, has a track on which the plate-carrying frame slides in a lateral direction. Surmounting this is a second track, B, at right angles to the first, on which the microscope carriage slides. These motions serve for measuring the two co-ordinates which are parallel to the plates. The remaining co-ordinate (E_0, Fig. 1) is

determined by measuring the parallax by an independent lateral motion of the right-hand plate.

In placing the plates, P_1 and P_2, in the frame, they are adjusted so that the lines connecting the hole marks at the top and bottom of the plate are parallel to the track, B. For this purpose, the plate-holders are mounted on the plate carriage so that they can be turned through a small angle by slow-motion screws, D_1 and D_2. In order to compensate for the difference in elevation of the two standpoints from which the plates were taken, the right-hand plate is adjustable vertically by the screw, C.

Lateral deviation is measured by the scale, X, vertical deviation by the scale, y, and distance, that is, parallax, by the scale, Z, to 0.001 mm. The parallax measurement must be made with the utmost accuracy, as the other two co-ordinates are derived from it. Its importance is analogous to that of quick and accurate distance measurement in tacheometry.

For viewing the plates there is a Helmholz tele-stereoscope in connection with a binocular microscope (power $6x$ and specific plastic $4x$). In order to be able to measure with the tele-stereoscope in the image plane of both eyepieces in the center of the field, a balloon-shaped measuring mark is fixed. This mark resembles a solid circle standing above a plus sign. When properly adjusted, the stereoscopic effect causes these two images to coincide and appear as a single image floating in space. With the shifting mechanism, the observer is able to place this mark on any desired point in the landscape. By turning H, it appears to move laterally; by turning V, it appears to move vertically; by turning Z, it appears to move to and fro. This artificial mark has the function of the rodman in a tacheometrical survey, with this difference, that it depends solely on the will of the observer and not on the capacity of the rodman; also, it is not influenced by wind or weather, and is not handicapped by roughness and inaccessibility of the territory to be surveyed.

It is important to notice that it is not necessary for the observer to have the power of stereoscopic vision, because, in placing the balloon mark on a certain point in the landscape, he first sets the point in the left ocular, then brings the mark into coincidence in the right ocular, before making a binocular observation, as in the case of those with one defective eye or with one eye especially trained.

Plotting Device.—The device for the plotting of the map (Fig. 6) is a strong mirror-glass plate on which a steel ruler, L_1, is pivoted at a point representing the left standpoint, M_1. There is also a ruler, L_2, which can be clamped in a direction parallel to the optical axis. Both are of thin saw-blade steel.

The Range-Finder.—The stereo-comparator has an advantage over another very useful surveying instrument, the Zeiss range-finder. The latter, invented and perfected by Dr. Pulfrich, was found very useful in checking the side measurements of the triangulation, the check measurements on the more important points in the photographic survey, and also in the preliminary measurement of distances in order

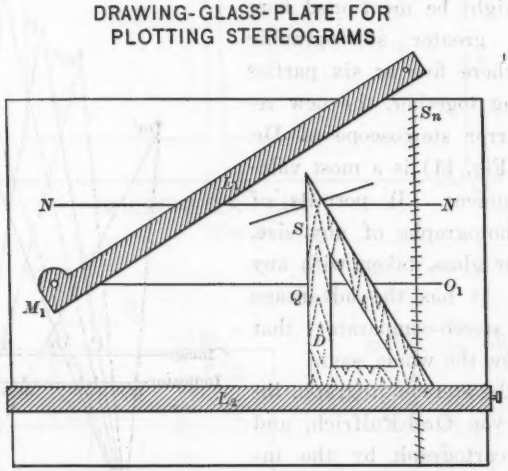


FIG. 6.

to make a proper selection of the base lines for the photographs, etc., taking into consideration the scale of plotting. The observer sees in the range-finder a stadia scale assuming the appearance of a solid zigzag line floating in space (Fig. 7). By this scale he is enabled to determine the distance of any point, "as if counting the poles of a telegraph line." He brings into coincidence with the point in question that mark on the scale which is apparently at the same distance. The range-finder in its usual form has a fixed scale.

The Stereo-Micrometer.—Another quite useful instrument, but of more theoretic-pedagogic interest, is the stereo-micrometer. It serves exceedingly well to explain the principle of the "wandering

or traveling mark" (Figs. 9 and 10) and the stereoscopic method of measuring distances in general. In this micrometer there is a "wandering mark" and pictures in fixed position relative to each other; in the stereo-comparator there are two fixed marks under which the plates are movable. The effect is practically the same.

Accuracy in working with the range-finder depends very much on the capability and practice of the observer. It might be mentioned that the ordinary stereoscope can only be used for small pictures taken with an ordinary camera with objectives separated by the usual interpupilary distance of 65 mm. Also, it might be mentioned here that, for greater stereographic surveys, where five or six parties are working together, the new reflecting-mirror stereoscope of Dr. Pulfrich (Fig. 11) is a most valuable instrument. It permits of viewing photographs of any size, on paper or glass, taken with any base line. It has the advantage over the stereo-comparator that one can view the whole scene.

FIXED MARKS IN THE ZEISS RANGE-FINDER.

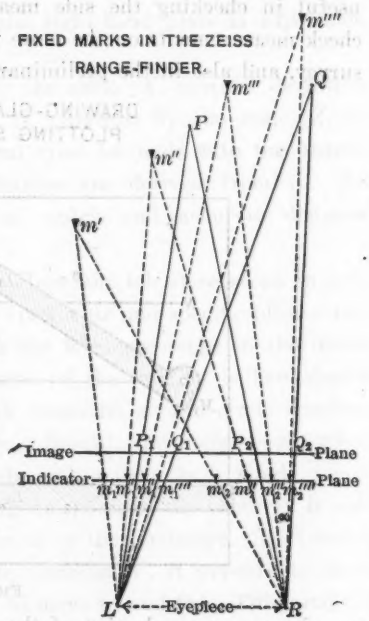

FIG. 7.

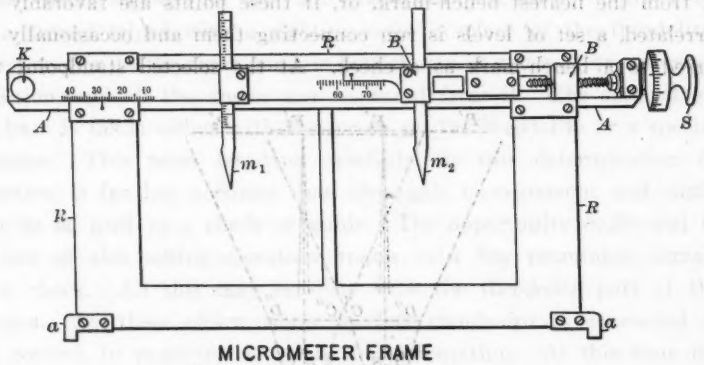
About the stereo-autograph, invented by von Orel-Pulfrich, and the stereo-cartograph by the inventor of the comparator, something may be said later, because they do not belong to the ordinary surveying outfit on account of their high cost.

GENERAL METHODS OF WORK.

It is necessary to distinguish between the work done in the field and that done in the office.

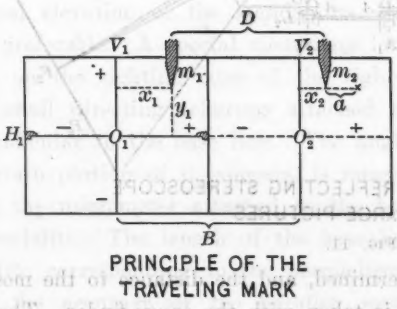
Field Work.—The outdoor work consists in the preparatory survey, that is, in selecting suitable and elevated auxiliary points. It is frequently desirable to run a line of bench-mark levels through the district to be surveyed. These can be referred to when necessary.

The natural characteristic points in the landscape, or the artificial signals to be erected, must be situated so that the resulting intersections are favorable for the triangulation; on the other hand, it is necessary that three, or better more, are visible from each standpoint, for the purpose of orientation and eventually for taking sights to the elevation marks.



MICROMETER FRAME

FIG. 8.



PRINCIPLE OF THE TRAVELING MARK

FIG. 9.

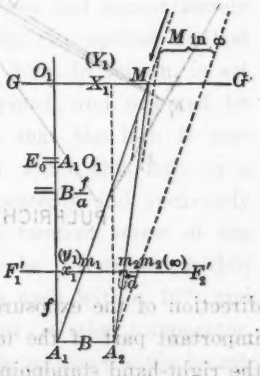


FIG. 10.

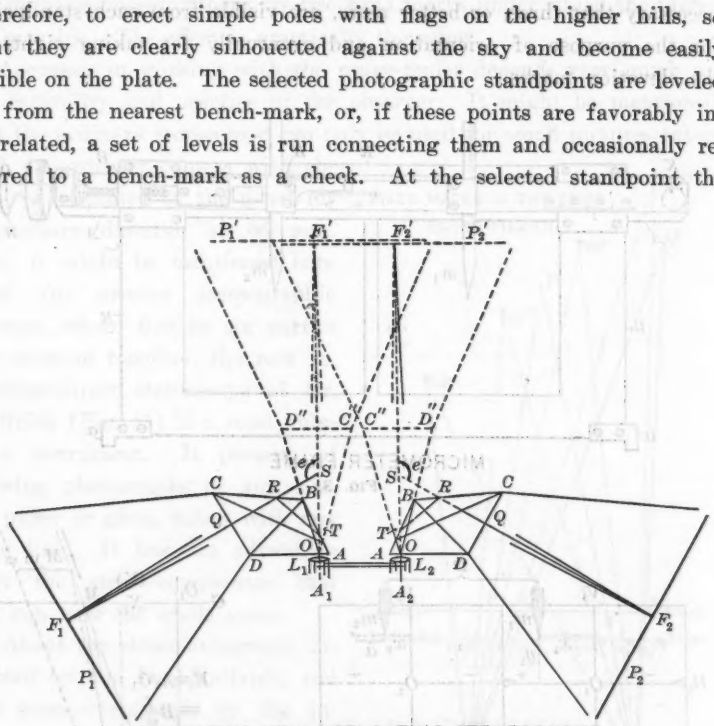
It is very desirable, but not always possible, to have such elevation control points on each plate. In selecting the trigonometrical points, the plan of attack with the camera must be considered beforehand. Occasionally, it is better, or even necessary, first to select the photographic standpoints, in order to be sure that they can be oriented in the auxiliary net thrown over the territory by resectioning or other-

wise. It is desirable, of course, to have these points visible on the plate. The erection of characteristic signals, as in first-class triangulation, would be too expensive for smaller distances. It is better, therefore, to erect simple poles with flags on the higher hills, so that they are clearly silhouetted against the sky and become easily visible on the plate. The selected photographic standpoints are leveled in from the nearest bench-mark, or, if these points are favorably interrelated, a set of levels is run connecting them and occasionally referred to a bench-mark as a check. At the selected standpoint the



PULFRICH'S NEW REFLECTING STEREOSCOPE FOR LARGE PICTURES

FIG. 11.

direction of the exposure is determined, and the distance to the most important part of the territory is taken with the range-finder. Then the right-hand standpoint is fixed at the length of the base in a direction perpendicular to the optical axis of the first exposure.

The base line bears a certain ratio to the average distance of the chief objects in the view and to the scale on which the map is to be plotted. Nevertheless, one need not be too strict, as the natural lay of the land usually renders a little more or less distance necessary. It is desirable that all stereograms of any one survey be of uniform accuracy.

It has proved very useful to mark these standpoints carefully. This makes it possible to return to the field and repeat exposures which have not proved entirely successful photographically, or to choose more favorable conditions of weather and light, without the necessity of repeating auxiliary measurements.

The photo-theodolite on the left standpoint gives the direction to all visible signals; on the right standpoint, higher or lower, is set up a second tripod with a sighting cone in place of the theodolite. The direction to the right point is best chosen at the zero or reference direction, and all the angles are measured from it. The azimuth of the base is taken either with a compass on the theodolite or a special compass. This must be done carefully, as this determination of direction is far less accurate than the angle measurement and ought only to be used as a check or guide. The opportunity ought not to be lost of also taking elevation angles to a few prominent signals as a check. All this may be done with the theodolite part of the camera. By these observations the left standpoint is connected to the control, in position, elevation, and orientation. At this time the base line measurement can be made. Direct steel tape measurement is possible with a short length of favorable ground and approximately equal elevation of the standpoints, but usually the optical method is preferable. A special measuring lath, 1 or 3 m. in length, is set up on the sighting cone of the right-hand tripod, and oriented by a small directing telescope attached to it so that the lath is perpendicular to the base line. The angle under which this lath, or a certain portion of it, appears, is measured repeatedly and accurately by the micrometer attached to the horizontal tangent screw of the theodolite. The length of the base line must be determined within 0.1%, corresponding to the parallelism of the axes within 10″, and to the accuracy of the parallax measurement in the comparator. According to the previously mentioned equations, an error in the length of the base enters proportionally and directly into all co-ordinates. The elevation angles to the right standpoint having been taken, the reduction of the base line to the horizontal can be done in the office. It must be expressly mentioned that the tripods should be set firmly. In hard and rocky soil, or in elevated positions exposed to the wind, extreme caution should be taken in this matter. Finally, the height of instrument (averaging 1.30 m.) from peg to center of objective, should

be measured. Having completed these auxiliary measurements, the actual exposure of the plate can be made, if the weather and sun permit.

The numerating device in the camera is set so as to record photographically the proper number of the exposure. Then the plate-holder is inserted, the slide is removed, and, by a special device, the plate is brought to an even contact with the plain brass rim of the back of the camera chamber, and locked in this position. Just before unstopping the lens, a final observation is made with the telescope pointing to the sighting cone at the other end of the base line, to make sure that the plate is in its proper plane. Immediately thereafter, the exposure is made, with all precaution against disturbing the apparatus.

It is advisable to make all the observations carefully, and always in the same sequence. An omission may necessitate remeasuring. After the exposure, the plate is drawn from its seat on the brass frame, the slide is inserted, and the holder is removed from the camera. Additional exposures can then be made at 30° with the first, or, if these are not desired, the camera and sighting cone are interchanged between the two ends of the base line. This is done without disturbing the tripods. On the right-hand standpoint the exposure can be be made without making further measurements, as the camera has been leveled and oriented.

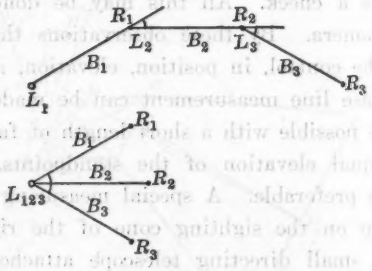


FIG. 12.

In order to make use of some especially favorable elevation for taking a panoramic survey, it is possible to use a series of base lines, either connected in a simple polygon or radiating from a single point (Fig. 12). In the latter case, the left standpoint serves for all base lines, and, of course, very greatly simplifies the field work; this, however, is not always possible on account of the lay of the land, as the selection of even a single base line is sometimes difficult.

A third possibility, recently used quite frequently, is, as already mentioned, making photographs equally inclined (usually at 30°)

to the base line, but still with the optical axes parallel. The writer always works with the horizontal axis, and prefers rather to shift the objective vertically, in order to make full use of the plate, or to bring the important features to the center of the plate, where the drawing is most accurate. It is best to set off the 30° deflection angle from the zero point of the circle, so that any error in the division has no influence on the parallelism of the axes, which must also be assured within 10″. It may be mentioned that, according to the investigation of von Hübel and Pulfrich on stereograms with parallel axes, a small deviation of both axes in the same direction gives a much smaller error than a convergence. Rough sketches, to indicate the territory included by an exposure, are convenient guides in making subsequent exposures during the interval before the development of the first ones. This will prevent the omission of narrow strips, or too much overlapping of consecutive pictures. With this the chief part of the field work is finished.

In surveying railway lines in mountainous districts, one may distinguish two principal cases:

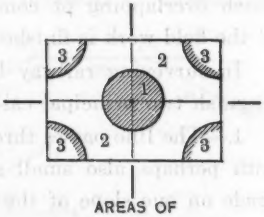
1.—The line passes through a fairly straight and broad main valley, with perhaps also small side valleys, and is on a fairly continuous grade on one slope of the valley. This is the most favorable case for the photographic survey, as the work can be done from the opposite side of the valley, with the different pairs of photographs, taken in approximately the same direction from nearly the same level.

2.—The line passes through a very tortuous valley, or across the topography, so that it frequently crosses the valleys. In this case the photographs must be made in all directions, and frequently from stations where it is difficult or impossible to include all points, especially those in the bottom of the valley, without an expenditure of too many plates which cover only small areas. In such a case it is best to commence the field work with a tacheometric survey of the lower ground, and, with this as a neucleus, to spread the survey by photographic means over the remaining higher territory. A combination of a rapid continuous tacheometric survey of the river with a photographic survey of all the higher and steeper parts is the most economical method. The contour lines are easily and safely developed from the natural guide line—the course of the river—thereby giving ample opportunity to check on the controls. There will be standpoints

near the bends where photographs can be taken looking into and over the valley for certain distances.

Office Work.—First, the triangulation must be calculated and plotted, and the trigonometric levels determined. The net having been plotted, say, on a scale of 1:10 000, copies of it should be issued to each field party, when several are simultaneously at work, in order to avoid confusion. The base lines, elevations of standpoints, orientation angles, etc., are calculated in the office. The standpoints must be denoted clearly and specifically in order to correspond to the numbers registered on the plates by the camera, independently of the plate-holder numbers. Base line No. 7, for instance, has a plate pair with the numbers I-3 and I-4, so that 50 base lines and 100 plates can be denoted by the numerating device.

In the purely photographic part, such as developing, intensifying, or reducing the negatives, making diapositives, prints, enlargements, etc., the photographer has to aim at clearness and accuracy, rather than artistic effect. If the staff is not skilled in photography, it is best to do this work in the field, in order to be able to replace spoiled plates without delay.



AREAS OF DIFFERENT ACCURACY

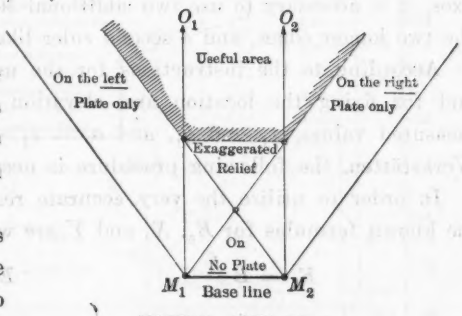
FIG. 13.

The chief work in the office is the measuring of the plates under the stereo-comparator. After a short practice it is possible to measure directly from the negatives. They are more exact, as all reproductions must lose in accuracy and sharpness. Nevertheless, it is advisable to make diapositives, first, in order to insure against the loss or breakage of the negative, and secondly, because sometimes it is possible to obtain good diapositives from weak negatives.

The value of a plate depends on the following considerations: All points which appear on one plate only, though that plate may be a good one, cannot be measured, as they cannot be viewed stereoscopically. Figs. 13 and 14 show the areas of relative accuracy and usefulness on any plate. The points of the very near foreground do not appear on any plate. For instance, those on the right plate and the left border of the left plate are useless. Those of the farther foreground show exaggerated relief, and are not suitable for measuring, as the parallax is too great. Points at very great distances become too in-

accurate, but can eventually be used for the mere topographical completion of the map.

In measuring the plate, the control points are considered first, if they are visible on the plate; and their co-ordinates are measured and compared with those on the triangulation map. If they are not visible, the distance, lateral deviation, and elevation are taken from the map, and the comparator is set to the corresponding scale readings, in order to see where the point falls in the view. Occasionally, it may happen that the image of the point can then be discovered near or coinciding with the balloon mark. At least, it can be observed whether the balloon mark assumes a position on the surface of the ground, or an impossible position in the air, or beneath the surface. Disagreements or errors must be first explained or removed; such precautions are absolutely necessary in order to avoid absurdities. After making sure that the check points agree, the measurements for the other points can be taken.



USEFUL AREA OF A NORMAL STEREO-EXPOSURE

FIG. 14.

In selecting the points needed for drawing the contours, either of two principles may be adopted: All points of equal parallax may be taken, or points of equal y-reading. This simplifies the work of noting and plotting by the elimination of one variable, in each case. The chief objection to such a method is that it is not flexible enough. It is similar to the old cross-profile method. The other principle is to make, in the shelter of the office, a tacheometric survey. This requires the judgment of the experienced topographer, and is a little more troublesome, as all three variables must be considered. However, this method was preferred by the writer for "normal" stereograms. When working in shifts, or in any case to avoid repetition or confusion, the points taken out may be marked on a print in red. The observer with the comparator must consider the scale of the map, and must in imagination travel into the scenery and select fairly evenly dis-

tributed points. Though the parallax can be read to 0.001 mm. and the x- and y-scales to 0.01 mm., it is useless to read to a greater degree of accuracy than can be plotted on the map.

A numbered list of the points, with their co-ordinates, is made and from it the points are plotted.

The plotting device consists of a glass plate, about 1 m. square, with paper pasted on both sides (Fig. 6). On this are drawn the divisions required for the construction of the points (Fig. 15). There is a metallic ruler, L_1, with millimeter divisions on the upper edge and pivoted at M_1 on a conical bearing attached to a metallic inlay in the glass plate. There is also a ruler, L_2, which can be clamped to the plate, and a triangle, D. It is arranged so that the plate can be used on either side. For the plotting of stereograms with inclined axes, it is necessary to use two additional 30° triangles with scales on the two longer edges, and a second ruler like L_2.

According to the instructions for the use of this drawing device, and for fixing the location and elevation of a point, P, from the measured values, x_1 and y_1, and $a = x_1 - x_2$, issued by the Zeiss Werkstätten, the following procedure is necessary:

In order to utilize the very accurate readings of the comparator, the known formulas for E_0, X, and Y are written as follows:

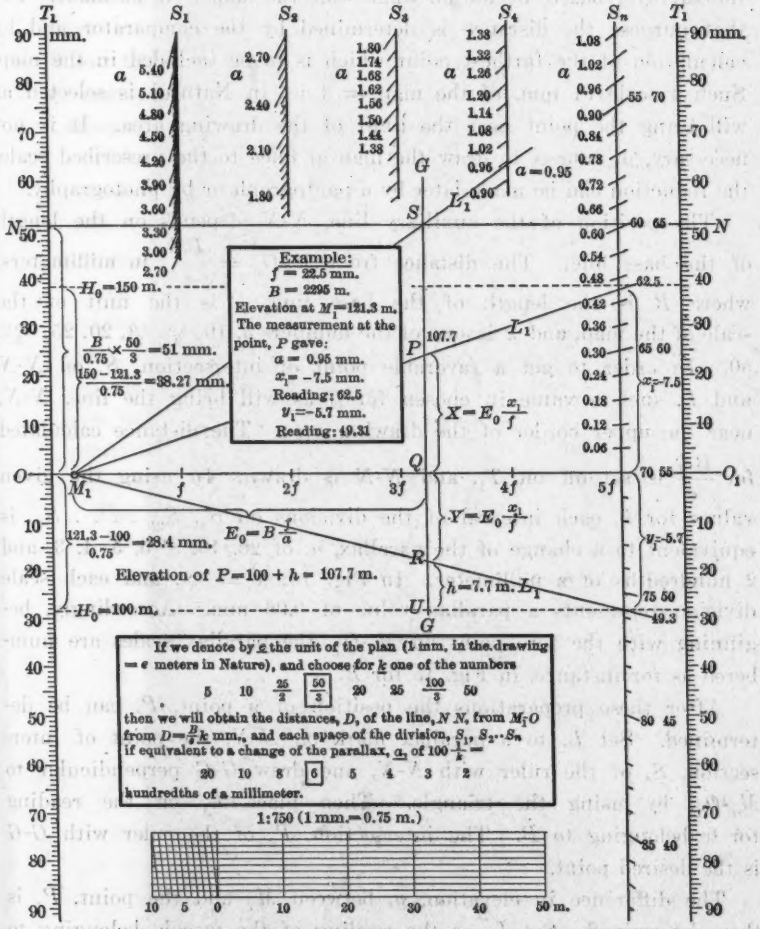
$$E_0 = B\frac{f}{a} \qquad E_0 = k\,B\frac{n\,f}{k\,n\,a}$$

$$X = E_0\frac{x_1}{f} \qquad X = E_0\frac{n\,x_1}{n\,f}$$

$$Y = E_0\frac{y_1}{f} \qquad Y = E_0\frac{n\,y_1}{n\,f}$$

The coefficients, k and n, will be explained later. M_1 always represents the left-hand station, M_1-O_1 the direction of the optical axis. Lay off from M_1 on M_1-O_1 (Fig. 15) the distance, f, the focus, in millimeters, repeated to the edge of the drawing. Through the points thus obtained draw perpendicular lines, S_1 S_2, . . . etc. Divide these S-lines so that the divisions on S_1 = 1 mm., on S_2 = 2 mm., on S_n = n mm., etc. The last line is divided throughout its length, the others only at the upper extremity. T_1 and T_1 are two millimeter scales with zero points on M_1-O_1. Thus each plate is prepared once for all. The actual plotting is done on tracing paper mounted over this. The cone pivot of the ruler, L_1, remains un-

covered. The scale, S_n, is now numbered for x and also for y, but the point on M_1-O_1 is not denoted by zero. The balloon mark of the comparator is set to cover the hole marks on the left topographic



LOCATION AND ELEVATION OF A POINT, P, BY MEANS OF THE MEASURED VALUES, x_1, y_1, $a = x_1 - x_2$

FIG. 15.

plate and then the verniers of the scales, x and y, are adjusted to read whole numbers. These readings are then the respective x- and y-values to be given the middle point of the scale S_n (70 and 55 in

Fig. 15). Starting up and down from this point, the remaining points of S_n are numbered. Both rows of figures are written on the right side of S_n. The figures on the left are to denote the parallax. Now the surveyor has to decide on what scale the map is to be made. For that purpose the distance is determined by the comparator and by calculation of the farthest point which is to be included in the map. Such a scale (1 mm. of the map = 1 m. in Nature) is selected as will bring the point near the limit of the drawing area. It is not necessary, of course, to draw the map at once to the prescribed scale, the reduction can be made later by a pantograph or by photography.

The position of the auxiliary line, N-N, depends on the length of the base line. The distance from M_1-$O_1 = \frac{B\,k}{c}$, in millimeters, where B is the length of the base line, c is the unit of the scale of the map, and k is one of the numbers 5, 10, $\frac{25}{2}$, $\frac{50}{3}$, 20, 25, $\frac{100}{3}$, 50. In order to get a favorable point of intersection, S, on N-N and L, such a value in chosen for k as will bring the line, N-N, near the upper border of the drawing area. The distance calculated for $\frac{B\,k}{c}$ is set off on T_1, and N-N is drawn. In using the given values for k, each interval of the divisions on S_1, S_2, ... S_n, is equivalent to a change of the parallax, a, of 20, 10, 8, 6, 5, 4, 3, and 2 hundredths of a millimeter. In Fig. 15, $k = \frac{50}{3}$, and each scale division represents a parallax value of 0.06 mm. Accordingly, beginning with the zero point on M_1-O_1, the parallax scales are numbered as for instance, in Fig. 15 for B.

After these preparations the position of a point, P, can be determined. Set L_1 to a parallax mark on N-N, the point of intersection, S, of the ruler with N-N, and draw G-G perpendicular to M_1-O_1, by using the triangle. Then place L_1 on the reading for x belonging to P. The intersection, P, of the ruler with G-G is the desired point.

The difference in elevation, y, between M_1 and the point, P, is then determined. Set L_1 at the reading of the y-scale belonging to P, mark R of the ruler, L_1, with G-G, and measure R-$Q = y$, by compass or glass scale. The absolute elevation, H, of the point, P, can be determined as done in the figure by a few auxiliary lines parallel to M_1-O_1 directly on the drawing. Another means of determining H directly is the millimeter division on the edge of the

steel triangle. The elevations are noted on a slip of paper beside the division, and the ruler, L_2, is placed so that the divisions in all positions of the triangle passing along L_2 are cut by the axis, M_1-O_1.

Sometimes the ordinates are better calculated if the progress of the work in plotting with graphical determination of the elevation is slower than that of the comparator readings, and an extra man can be engaged on it. Of course, one could try at once to construct the contours on these tracing paper "point sheets", but it is preferable to prick off all these points from the various single sheets into the general map. Certain portions of the ground may be covered from several standpoints. Occasionally, the points from different sheets may supplement and check each other; others can be dispensed with. In any case it is good, in working out many stereograms of difficult country, to plot the photographic base lines beforehand on the triangulation map with all the angles covered.

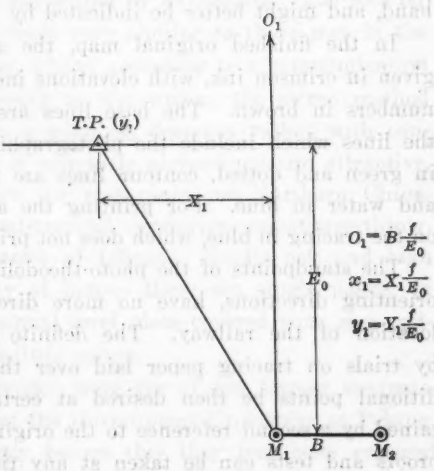


FIG. 16.

The observer using the comparator consults the map before starting work on a new pair of plates, takes out the co-ordinates of the control points, assures himself which parts of his section are shown on his plate alone and which by others once or twice. Of course, it is not quite easy, especially if the observer has not been in the country, to recognize these areas from the orthogonal projection of the map in the comparator, with its limited field of view. Here the new reflecting stereoscope could be used with great advantage.

Characteristic points in a doubly or triply covered section are extremely well suited for special control checks of base lines.

As mentioned previously, it is not absolutely necessary to observe the two plates simultaneously, as the balloon mark of the left, and afterward that of the right, microscope can be successively set on a point; but it is highly desirable that the observer be able to see

stereoscopically, as he is thereby enabled to place the mark as conveniently as though he were able actually to wander at will through the country represented in the photographs.

In photographic surveying no special methods of drawing the contours are involved, as they are filled in from the points obtained, just as from those obtained by any method of surveying. In a preliminary railway survey one usually has to deal with a strip of country from 300 to 700 m. in width, but, in general topographic and geological surveys one has to measure extended areas. For the territory of the most probable line, the greatest accuracy, relatively, is necessary, but, for the more distant country, only a rough approximation is needed. Such supplementary work can be done in the field by free-hand, and might better be indicated by dotted lines.

In the finished original map, the auxiliary triangulation net is given in crimson ink, with elevations indicated in red, and the control numbers in brown. The base lines are drawn in solid green lines; the lines which include the photographic angle of each exposure are in green and dotted, contour lines are in brown, buildings in black, and water in blue. For printing the auxiliary lines may be drawn on the tracing in blue, which does not print out.

The standpoints of the photo-theodolite, the base lines, angles, and orienting directions, have no more direct interest after the definite location of the railway. The definite line is determined as usual by trials on tracing paper laid over the original map. Should additional points be then desired at certain places, they may be obtained by a second reference to the original photographic plates. Also proofs and tests can be taken at any time when doubts arise. This is a very great advantage over the ordinary tacheometric method, where a revision of the map means an entire remeasurement in the field. It is even possible to seek the single points of the located line in the office by using the plates, as the map gives the parallax and the lateral deviation. For a certain value of a or x, it is only necessary to set the balloon marks on the ground in order to obtain directly the ordinate required for the plotting of the profile. In this way all inaccuracies, produced by the more or less free ideal design of the contours, are avoided.

The possibility of plotting on a larger scale certain places, where perhaps structures are to be erected, depends on whether the length

of the base line is sufficient. Cross-sections, also, can be easily taken. Finally, it is possible to transfer points of the line backward from the map into the photographic plates or prints, so that, in the pictures one may follow the proposed line over hill and valley.

THE STEREO-PHOTO-GRAMMETRIC SURVEY OF THE VALLEY NEAR ICHANG.

The foregoing explanations are given in great detail on account of the newness and possible importance of the subject. They deal with the general working plan, the theory of stereo-exposures, the instruments used, and the methods. Something may now be added about the survey of the rocky valley near Ichang.

Not far from Ichang commence the famous gorges of the Yangtze Kiang, noted among travelers, but feared by navigators. The locality and conditions for the survey were very similar to those met in the building of the Bagdad Railway, where, according to a communication from Ph. Holzman and Company to the writer, the stereo method was also used. The Ichang is a winding, deep-cut valley, with canyons and gorges. The scenery is extremely picturesque and attractive, especially to one arriving from the vast plains of Northern China. The slopes are clothed with semi-tropical vegetation, sometimes thinly, and sometimes with dense masses of foliage. Needle oak and high ferns abound. In the vicinity of houses there are single palms, in the bottom of the valley occasional level plots covered with rice paddies, and on the flatter slopes a little cotton.

The collaborators of the writer were six of his former students, just graduated from his class at the Government University at Peking, and speaking English. Shortly before this they had been engaged with the writer on another (but smaller) survey by the photo-stereographic method. These men acted as party heads. The three German engineers were not acquainted with the method. The ten students from Hupeh did not speak a European language, and were not acquainted with German instruments in general, or with the stereographic method.

Unfortunately, the writer could make the survey only during his vacation, namely, in July and August. These months are in every respect the most unfavorable ones in the Yangtze Valley, which, even at the best, has a bad reputation climatically. The heat is perhaps not considerably higher than it may be occasionally in North China,

but the greater humidity causes greater discomfort. Even with a clouded sky, the atmosphere is extremely sultry. In this glowing valley it is practically impossible for a European to work in the direct sun between the hours of 11 A. M. and 3 P. M. Frequent cloudbursts swell the river so that it is impossible to reach the field stations.

The whole party found quarters in a temple, where the photographic plates were developed and worked out. Provisions were difficult to obtain, as there was no fresh meat except chickens, and no vegetables. The muddy water from the rice fields caused ailments of the digestive organs. Nevertheless, serious troubles were prevented by the use of tinned provisions and by filtration of the water.

The most serious and unpleasant drawback was the effect of the heat and moisture on the photographic process. Work in the dark-room could be carried out successfully only during the cooler morning hours, between 2 A. M. and sunrise. The Chinese photographer was not very experienced, and worked slowly. The transport of the good and only recommendable Agfa Chromo Isolar plates was unexpectedly delayed, and the party had to start the work and make trials with many kinds of ordinary dry plates, none of which proved very successful, as some were old and all were improperly packed for the climate. There were some periods of from 6 to 10 days when the sky was clouded. Nevertheless, exposures were made in order to keep things moving. The negatives obtained, however, were so flat that the measurements were made with difficulty. After the arrival of the Agfa plates the negatives were uniformly exceedingly clear and sharp. The emulsion had a much finer grain and seemed to be more heat-resisting. From each plate several prints taken at the left standpoint were made, on which to mark out the points, etc. The new model of the stereo-comparator is equipped with a device for making these marks automatically. A pair of pictures is used for viewing in the reflecting stereoscope.

The negatives, diapositives, and prints were kept in double plate envelopes, especially made for that purpose and printed as field note books. They were made of tracing cloth, and served to protect the plates from damage. The printed record form on each envelope contains all the observations in the field and all the calculations necessary for working out the plates. It is advisable to write the field observations directly on these envelopes, in order to avoid possible confusion in transferring notes.

The theodolite at the disposal of the party was a small light instrument, with short focus (about 100 mm.) and small circle. It was not intended for preliminary railway surveys, but for explorers on general topographic work. In the course of the work it was discovered that the leveling screws were too small in proportion to the sensitiveness of the bubble tube (10″), the power of the telescope was too small (10x), the springs of the micrometer screws were too weak,

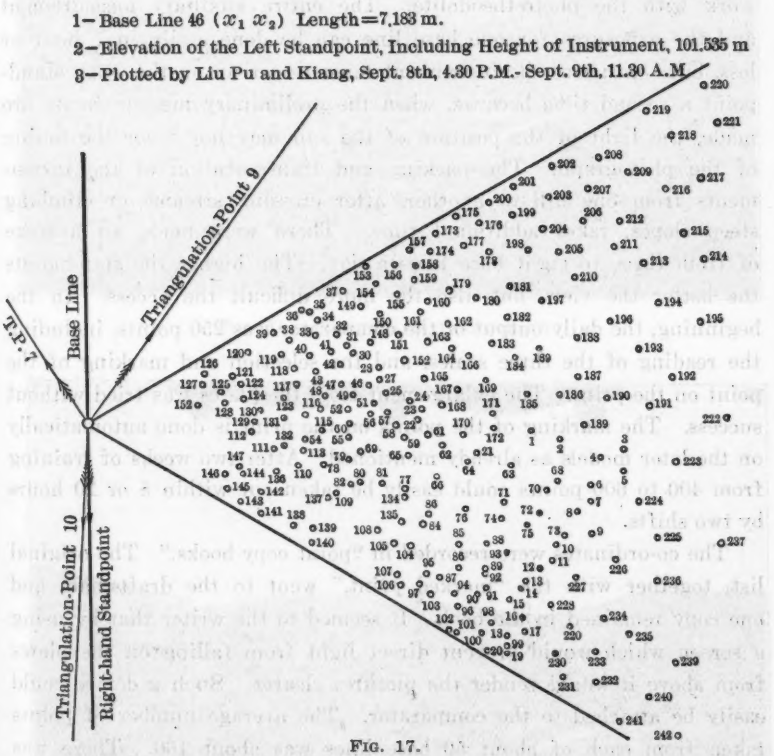

FIG. 17.

and the feet of the tripod too small for a firm setting. Also, the compass did not work satisfactorily. A desirable improvement would be a second bubble tube in the direction of the optical axis as well as a special sighting attachment, such as a direct-vision view-finder. The image on the glass plate is very dark on account of the small stop used. Therefore, the Zeiss Werkstätten proposes, as an apparatus especially suited to railway work on the scale of 1:5 000 to 1:2 500,

a photo-theodolite with $f = 190$ mm., using 13 by 18-cm. plates, with a special device for making exposures turned at 30° from the base line. In this way the image angle can be increased to 110°. In spite of the above-mentioned limitations of the instrument, the accuracy was sufficient for the short distances of the survey, as was proved by the numerous checks.

It is not easy to state the exact time required for the ordinary work with the photo-theodolite. The entire auxiliary measurement and the exposures for one base line can be done easily in 1 hour or less, but sometimes the instrument must be set up on the same standpoint a second time because, when the preliminary measurements are made, the light or the position of the sun may not favor the taking of the photograph. The packing and transportation of the instruments from one hill to another, after crossing streams or climbing steep slopes, takes additional time. There were made an average of from three to eight base lines a day. The higher the standpoints the better the view, but also the more difficult the access. In the beginning, the daily output of the comparator was 250 points, including the reading of the three scales, and the selection and marking of the point on the print. The enlargement from the plates was tried without success. The marking of the points on the print is done automatically on the later models as already mentioned. After two weeks of training from 400 to 600 points could easily be taken out within 8 or 10 hours by two shifts.

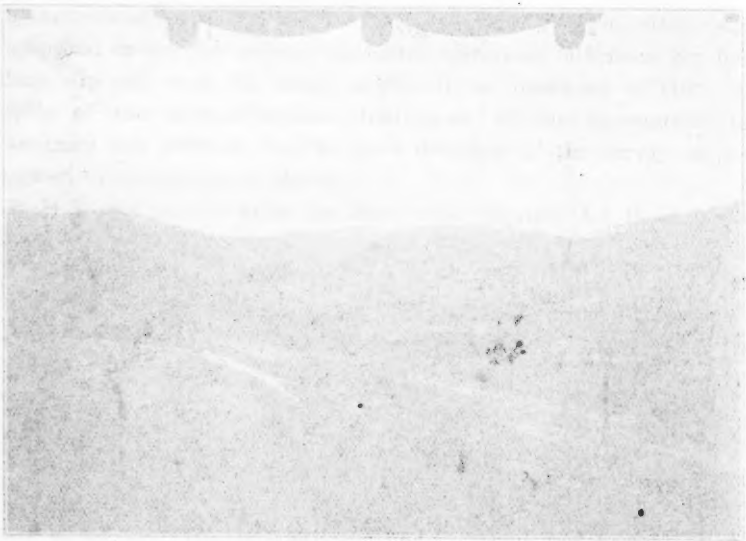
The co-ordinates were recorded in "point copy books." The original list, together with the "marked print," went to the draftsman, and one copy remained in the book. It seemed to the writer that by using a screen which would prevent direct light from falling on the plates from above it would render the pictures clearer. Such a device could easily be attached to the comparator. The average number of points taken from each of about 50 base lines was about 160. There was an average of one point per 25 sq. m. The area of the drawing plate was about 1 sq. m.

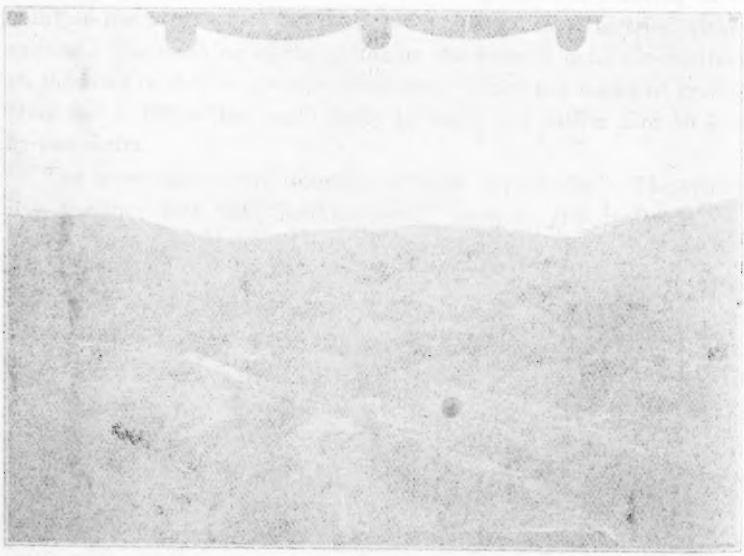
For the scale adopted, 1:2 500, and with a maximum distance of 1 km., a sheet 40 by 40 cm. was required.

After finishing the survey of this rocky valley, work on the less rough country was commenced, and there the conditions were a little different. It was to be mapped on the scale of 1:5 000. It was in-

FIG. 18.—RIGHT-HAND PHOTOGRAPH.

FIG. 19.—LEFT-HAND PHOTOGRAPH.
Base Line 46 (x_1 x_2). Length = 7.183 m.
(From Figs. 18 and 19 the Point Sheet, Fig. 17, was Plotted.)





tended to make from all base lines further exposures with the optical axes turned at 30°, for the purpose of trying out this scale with the now more experienced staff and with the new plotting method, recently published by Dr. Pulfrich. It would have been very valuable indeed to continue in this country (which also could have been surveyed tacheometrically) with the newly arrived fresh and uniform plates and during the cooler autumn weather. Unfortunately, the writer was obliged to return to Peking earlier than he intended, in order to resume his lecture work. The entire result of the work consisted of the following collection of data.

(1) Level notebooks for the bottom of the valley and photographic standpoints.
(2) Angle measurements of triangulation and trigonometric levels.
(3) Calculations of triangulation and trigonometric levels.
(4) Point co-ordinate books, with calculated elevations.
(5) "Point sheets" (tracing paper, 40 by 40 cm.) with "point prints."
(6) Supplementary tacheometric notes.
(7) Photographic material; for each base line three double envelopes containing respectively, negatives, diapositives, and prints.
(8) Finished map, and prints from it.

The whole material was collected and filed in an especially designed chest of drawers, Fig. 21, so that reference and revision could be effected readily.

Conclusions.

The result of this first trial in applying stereoscopy to preliminary railway surveys in China can be considered as satisfactory and encouraging, notwithstanding that the instruments were not quite suitable, that the staff was inexperienced, and that the climate was unfavorable. Although the territory could have been surveyed by tacheometry, it would have required seven times as long. The greatest advantage is that it is not necessary to enter the whole of the territory surveyed, and that the outdoor work takes relatively little time. Later, the working out of the plates for this survey could have been done at Hankow, where there were cool rooms, ice, and electric fans. An improvement for future work might be the use of a larger theodolite,

the greater weight of which would not be significant in the Orient where cheap coolie labor is to be obtained.

The costliness of the necessary precise photographic instruments is a relatively insignificant item of the capital required for the construction of a great railway, especially in China. The saving in capitalized interest by any acceleration of the construction more than justifies such an expenditure. For a like reason, even very expensive apparatus, such as Pulfrich's "stereo-cartograph," might be very advantageously utilized. This instrument plots the selected points automatically, through an ingenious system of levers connecting the scales of the comparator with a marking apparatus on the map.

The von Orel-Pulfrich "stereo-autograph" goes one step farther, as it enables the observer to move the balloon mark along the lines of equal elevation in the view, and at the same time plots the contour lines automatically.

Both these instruments have this great advantage, that they not only make possible the working out of "normal" stereograms, but also of those with equally turned axes, or even with convergent axes, with equal facility. This, as mentioned previously, is not possible in ordinary plotting. These convergent photographs are of special value, as they present the greatest stereoscopic field. If this latter apparatus (price 25 000 marks = $6 250 gold) could have been used, the whole work described herein could have been done in a fraction of the time, by one man instead of four, and more accurately. In the transfer of the points from the point sheets, and in the interpolation of the contours, for example, there are sources of errors to which the plotting engine is not subject.

China is a field in which the photogrammetric method is especially suitable on account of its vast areas of mountainous country. In the North these mountains are bold and bare, in the South and central part they are wooded, but so sparsely that the surface of the ground is sufficiently visible. Moreover, the engineer is not provided by the Government with serviceable ready-made maps as in most Western countries.

The railways are beginning to spread from the seaboard across this mountainous country in all directions. The German section, from Hankow to Ichang, is still for the greater part in flat country, only the part herein described being mountainous, but the American section,

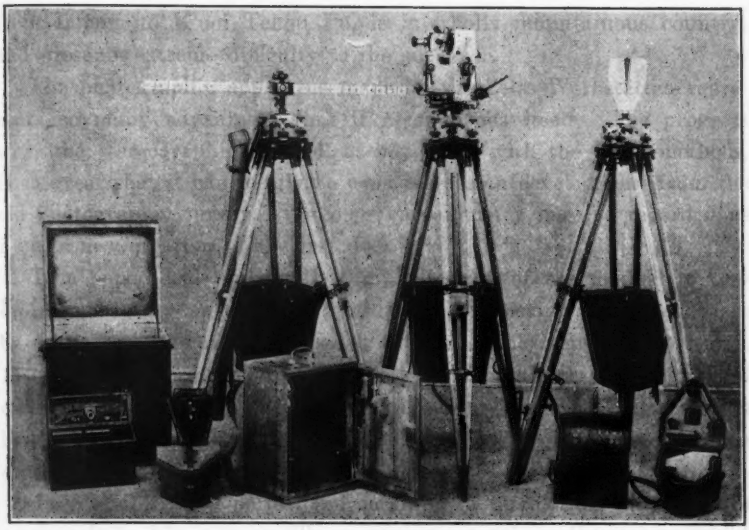


FIG. 20.—EQUIPMENT FOR A STEREO-PHOTO-GRAMMETRICAL SURVEY.

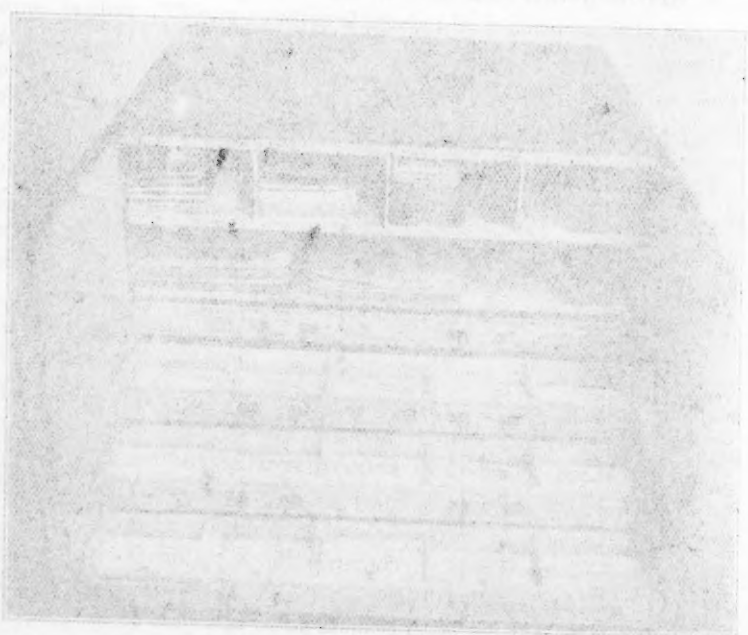
FIG. 21.—CHEST OF DRAWERS FOR STORING MATERIALS USED IN A STEREO-PHOTO-GRAMMETRICAL SURVEY.



from Ichang to K'uei Tchou Fu, is in wholly mountainous country, and presents extreme difficulty to the surveyor.

The photographic apparatus made by the Zeiss Werkstätten represents so many advantages that it recommends itself. The progress with the stereographic method, as compared with the older methods, is so great that it can hardly be considered as a development from the old photographic survey. Photo-stereogrammetry may be regarded as a quite new creation of the last decade.

This paper deals only with the application of the method to preliminary railway survey. With this its engineering possibilities are by no means exhausted. Instead of the simple unrelated pictures, 18 by 30 cm., formerly taken at intervals to indicate the progress of earthwork or structures, stereographic pictures can be taken from a base line fixed once for all. Such pictures would give a much clearer conception of the progress of work.

Besides this, they permit the checking of quantities, statements of earthwork in big cuts or fills, masonry masses, or dimensions which will later be inaccessible, and the agreement of structure to design, and this can be done quickly and accurately at headquarters. The chief engineer of a railway in China will be often unable to visit the field at the most desirable time, on account of the great distances, difficulties of travel, unfavorable climate, etc., and the demand for his presence at headquarters. In such cases the stereoscope will be of especial service, as it will answer his questions accurately. It brings country formerly quite impracticable within the range of an economic survey. The civil engineer frequently has to enter new lands, and will have to make himself familiar with this, the newest branch of surveying practice.

A METHOD OF DETERMINING STORM-WATER RUN-OFF.

By Charles B. Buerger, M. Am. Soc. C. E.

To be Presented October 7th, 1914.

Synopsis.

The rational method of determining storm-water run-off, as introduced by Emil Kuichling, M. Am. Soc. C. E., and modified in various particulars by designers in the United States and abroad, has usually given satisfactory results. It is not very widely used, however, and the formula methods, of which the Bürkli-Ziegler and the McMath are the most popular, are most generally used, in spite of the common realization of the fact that the results given by them lack consistency, and are very erratic and unreliable. The popularity of these insufficient formulas, notwithstanding their drawbacks, indicates that a formula which will give results reasonably close to those obtained by the rational method will be acceptable for service, even though of somewhat complicated form.

The writer has developed a formula for storm-water run-off of the form

$$q + N q^{\frac{4}{5}} = P$$

in which q is the run-off, in cubic feet per second per acre, and N and P are functions of the variable elements of topography, rainfall,

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

etc. Diagrams are given which afford a ready means of obtaining results from this formula.

The writer compares the results obtained by this formula with the gaugings in Rochester by Mr. Kuichling, the Birmingham gaugings by Mr. Lloyd Davies, the Evanston gaugings by C. C. Saner, Assoc. M. Am. Soc. C. E., the New York gaugings by Rudolph Hering, M. Am. Soc. C. E., the St. Louis observations by Robert E. McMath, M. Am. Soc. C. E., the Chicago observations by C. D. Hill, M. Am. Soc. C. E., and others; and notes the variations and discrepancies between observations and calculated results by the new formula. He considers that the results given by his formula are reasonably near to those of the gaugings, and that they may be considered an acceptable equivalent to those determined by the cut-and-try rational method.

Introductory.

At the present time much thought is being devoted to the question of storm-water drainage. Many large cities, such as New York, Chicago, St. Louis, Cincinnati, and others, are studying their storm-water systems, and in some cases are rebuilding where time has proved earlier designs to be inadequate.

Much of the drainage work done throughout the United States, even for large cities, does not have the benefit of such study, but is based on formulas entirely unsuited to the particular local conditions.

On this subject, it has been remarked, with some appearance of justice, that a refinement of methods in the calculation of storm-water run-off is not warranted by any experimental data now available; and it is implied that present methods are good enough when bearing in mind the meagerness and inconsistency of field determinations available to check these methods. It does not appear, however, that the best possible use has been made of existing gaugings.

Existing Methods.

Broadly speaking, two methods of attacking this problem are in customary use: The first is the so-called rational method, with its manifold modifications and variations; the second is the formula method. The rational method was publicly introduced by Mr. Kuichling in 1889.* Mr. August Frühling has given the most complete

* *Transactions*, Am. Soc. C. E., Vol. XX, p. 1.

and satisfactory exposition of this method.* Modified rational methods have been elucidated by Mr. E. E. Wallington Butt,† Mr. Carl H. Nordell,‡ Mr. Maximilian Vicari,§ (the Hauff method), C. E. Grunsky, M. Am. Soc. C. E.,|| Mr. Jean Balcomb,** W. W. Horner, Assoc. M. Am. Soc. C. E.,†† and Messrs. R. O. Wynne-Roberts and T. Brockman.‡‡

The various applications of the rational system differ much in detail of use, but they all follow the system of reproducing, by cut-and-try methods, the existing conditions, to the point of finding corresponding sewer grades, sizes, and assumed rainfall curve and rain absorption or retention.

It is almost everywhere conceded that the rational system, in any of its forms, if used with proper discretion, will give very satisfactory results. It is worth noting, however, that it has not received the widest use, and that formula methods are much more popular. For this there is the reason that the rational system is relatively laborious, and requires, in addition, a material exercise of judgment. Not but that frequent practice will rapidly teach facility of application; but the formula systems have always carried, and probably always will carry, the popular support, because of their convenience and mechanical system of use.

Many run-off formulas have been proposed, among which may be listed:

Hawksley (or Bazalgette):

$$\log. d = \frac{3 \log. A + \log. N + 6.8}{10} \quad \ldots\ldots\ldots\ldots (1)$$

Where d = diameter of sewer, in inches;

N = length of sewer per foot of drop;

and A = area, in acres.

Bürkli-Ziegler:

$$q = C R \frac{S^{0.25}}{A^{0.25}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

* "Handbuch der Ingenieurwissenschaft: Der Wasserbau;" Die Entwässerung der Städte, Leipzig, 1910 (William Engelmann).

where q = run-off, in cubic feet per second per acre;
C = an empirical constant;
S = slope, in feet per 1 000 ft.;
A = area, in acres;
and R = rainfall, in inches per hour.

Adams:

$$q = C\,R^{0.83}\,\frac{S^{0.083}}{A^{0.167}} \qquad (3)$$

McMath:

$$q = C\,R\,\frac{S^{0.20}}{A^{0.20}} \qquad (4)$$

New York diagrams (Hering):

$$q = C\,R\,\frac{S^{0.27}}{A^{0.167}} \qquad (5)$$

W. C. Parmley, M. Am. Soc. C. E.:

$$q = C\,R\,\frac{S^{0.25}}{A^{0.167}} \qquad (6)$$

C. E. Gregory, Assoc. M. Am. Soc. C. E.:

$$q = 2.8\,\frac{S^{0.187}}{A^{0.14}} \qquad (7)$$

$$q = \frac{\frac{105\,C}{L}}{84\,\sqrt[5]{A\,S^2}} + 25 \qquad (8)$$

When L = greatest length of sewer, in feet.

All these formulas have this feature in common, that they were devised to represent the conditions at some particular locality, and within certain limiting ranges of slope, area, length, rainfall, and imperviousness. There is no reason to doubt that, for the conditions they were formed to meet, they gave results approximating the facts. Some of them, notably the Bürkli-Ziegler and the McMath, have found a wider application than is reasonably warranted.

An engineer can use a formula with some confidence if sufficient experience is available to assure him that his constants are the proper ones and that he is applying it within its allowable range. In a city, say, like New York, where any formula has been successfully used (and that implies that resulting construction has been neither too large nor too small), and where the conditions of use being con-

sidered are within the range of previous practice, the engineer can be satisfied to design additional storm sewers on the same basis; but, unfortunately, it is only occasionally that it can be determined whether or not the design has been a proper one, from an engineering standpoint.

A great many of the designs for storm-water sewers do not come in this class. They are made for localities where there is little precedent to serve as a guide. The attempt to use a formula of the ordinary design has here at times resulted disastrously. The data of topography and rainfall, of course, are at hand, but, in a new territory, the proper selection of the constants is a matter of much difficulty. For instance, in the exponential formula (McMath type), Cleveland has used a value of $R = 4.0$; New York a value of 2.75; and Chicago a value of 1.0. The rainfall in these cities does not differ materially, and in no way accounts for this variation in the assumed R.

It is not necessary at this late date again to point out the limitations and discrepancies of any of the various formulas used. These are generally realized. In spite of this, it is probable that the great bulk of storm-water drain design is still being executed on the basis of these discredited methods. It is not unusual to read an account of a storm-water drainage system in which all details of construction have been studied most carefully, and where materials, slopes, grades, strength, and other factors are fully worked out. The basis of design —the determination of the needed sizes—will be dismissed in a short paragraph stating that the Bürkli-Ziegler or McMath formula was used, with certain constants; and it is likely that, for a mountainous rocky district of small size, the same constants may be used as for a flat beach town of large extent. It seems to be established that the general preference is for the use of some kind of a formula, and that a reasonably correct and comprehensive one should be an acceptable substitute for the ordinary rough approximations.

There is a need for a formula of general application which can be used in a new locality with some reasonable assurance that it will be fairly appropriate, will be applicable for large areas or small, flat or steep slopes, and heavy or light rainfalls. The results given by such a formula must be compared fairly with the best of experimental information of storm-flow gaugings, and appear to be an envelope

where q = run-off, in cubic feet per second per acre;
C = an empirical constant;
S = slope, in feet per 1 000 ft.;
A = area, in acres;
and R = rainfall, in inches per hour.

Adams:

$$q = C\,R^{0.83}\,\frac{S^{0.083}}{A^{0.167}} \quad \ldots\ldots (3)$$

McMath:

$$q = C\,R\,\frac{S^{0.20}}{A^{0.20}} \quad \ldots\ldots (4)$$

New York diagrams (Hering):

$$q = C\,R\,\frac{S^{0.27}}{A^{0.167}} \quad \ldots\ldots (5)$$

W. C. Parmley, M. Am. Soc. C. E.:

$$q = C\,R\,\frac{S^{0.25}}{A^{0.167}} \quad \ldots\ldots (6)$$

C. E. Gregory, Assoc. M. Am. Soc. C. E.:

$$q = 2.8\,\frac{S^{0.187}}{A^{0.14}} \quad \ldots\ldots (7)$$

$$q = \frac{\frac{105\,C}{L}}{84\,\sqrt[5]{A\,S^2}} + 25 \quad \ldots\ldots (8)$$

When L = greatest length of sewer, in feet.

All these formulas have this feature in common, that they were devised to represent the conditions at some particular locality, and within certain limiting ranges of slope, area, length, rainfall, and imperviousness. There is no reason to doubt that, for the conditions they were formed to meet, they gave results approximating the facts. Some of them, notably the Bürkli-Ziegler and the McMath, have found a wider application than is reasonably warranted.

An engineer can use a formula with some confidence if sufficient experience is available to assure him that his constants are the proper ones and that he is applying it within its allowable range. In a city, say, like New York, where any formula has been successfully used (and that implies that resulting construction has been neither too large nor too small), and where the conditions of use being con-

sidered are within the range of previous practice, the engineer can be satisfied to design additional storm sewers on the same basis; but, unfortunately, it is only occasionally that it can be determined whether or not the design has been a proper one, from an engineering standpoint.

A great many of the designs for storm-water sewers do not come in this class. They are made for localities where there is little precedent to serve as a guide. The attempt to use a formula of the ordinary design has here at times resulted disastrously. The data of topography and rainfall, of course, are at hand, but, in a new territory, the proper selection of the constants is a matter of much difficulty. For instance, in the exponential formula (McMath type), Cleveland has used a value of $R = 4.0$; New York a value of 2.75; and Chicago a value of 1.0. The rainfall in these cities does not differ materially, and in no way accounts for this variation in the assumed R.

It is not necessary at this late date again to point out the limitations and discrepancies of any of the various formulas used. These are generally realized. In spite of this, it is probable that the great bulk of storm-water drain design is still being executed on the basis of these discredited methods. It is not unusual to read an account of a storm-water drainage system in which all details of construction have been studied most carefully, and where materials, slopes, grades, strength, and other factors are fully worked out. The basis of design —the determination of the needed sizes—will be dismissed in a short paragraph stating that the Bürkli-Ziegler or McMath formula was used, with certain constants; and it is likely that, for a mountainous rocky district of small size, the same constants may be used as for a flat beach town of large extent. It seems to be established that the general preference is for the use of some kind of a formula, and that a reasonably correct and comprehensive one should be an acceptable substitute for the ordinary rough approximations.

There is a need for a formula of general application which can be used in a new locality with some reasonable assurance that it will be fairly appropriate, will be applicable for large areas or small, flat or steep slopes, and heavy or light rainfalls. The results given by such a formula must be compared fairly with the best of experimental information of storm-flow gaugings, and appear to be an envelope

of the bulk of the gauging results, rather than a mean line through them, in order to show a fair margin of safety.

It is not to be expected that such a formula can be a very simple expression; but this sort of complication is not a heavy deterrent to general use, if the results command confidence, as is evident by the general use of the Kutter formula.

The writer has developed such an empirical formula for storm-water run-off, and it is presented herein, together with a detailed comparison with all published gaugings available to him.

The Writer's Run-Off Formula.

q = the run-off, in cubic feet per second per acre;

L = length of longest sewer run, in feet;

C = a coefficient, the ratio of rainfall eventually reaching the sewers to the total rainfall;

A = area, in acres;

S = average slope of longest sewer, L, in feet per 1 000 ft.;

m = average slope of ground surfaces to sewer inlets, in feet per 1 000 ft.;

K = inches of rainfall per hour, lasting for a period of 1 hour, which sewers are to discharge.

$$N = \frac{L}{79 \sqrt[5]{C A S^2} \left(24 + \frac{16}{\sqrt{m}}\right)} \quad \ldots\ldots\ldots\ldots (9)$$

$$P = \frac{3.33 \sqrt{m}\, K C}{\sqrt{m} + 0.87} \quad \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

$$q + N q^4 = P \quad \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

Comparison with Run-Off Data.

The validity of a formula of this type rests only on its corroboration by the best of available data. A full coincidence, of course, cannot be expected. The data are scanty, not consistent in themselves, and not always such as to be entirely credible; but it is necessary that the formula be compared with the information we have for all known widely varying conditions.

KUICHLING'S ROCHESTER GAUGINGS.*

Mr. Kuichling's data are fairly full, but very far from being complete. It is necessary at times to estimate certain values as the probable ones, and where that is done a note to that effect is made.

District IV.—Size, about 4 800 by 1 200 ft.; population, 32 per acre; area, 128.67 acres; average street grades, 1 in 130; sewer grades, 1 in 50 to 1 in 630; time to flow through longest sewer, 18 min.; time to reach sewer, 8 min.

$A = 128.67$;
$L = 5\,000$ ft. (estimated);
$m = 7.7$;
$S = 2$;
$C = 0.34$;
I, for time of concentration (26 min.), from Kuichling's Plate I, $= 1.55$;
K, from Kuichling's Plate I, $= 0.87$.

District I.—Area irregular, 356.94 acres; about one-half of the area has a population of 35 per acre; remainder, agricultural and thinly settled; grade of sewered streets, 1 in 150; sewer grades, 1 in 47 to 1 in 910; time to flow through sewers, 34 min.; time to reach sewers, 10 min.

$L = 9\,300$ ft. (estimated);
$m = 6.7$;
$S = 1.4$ (estimated);
$C = 0.25$;
I (for 44 min.) $= 1.0$;
K (as before) $= 0.87$.

District X.—Long, narrow strip; area, 25.12 acres; population, 40 per acre; surface grades, 1 in 172; sewer grades, 1 in 70 to 1 in 330; time to flow through sewers, 10 min.; time to reach sewers, 6 min.

$L = 2\,000$ ft. (estimated);
$m = 5.8$;
$S = 4.0$ (estimated);
$C = 0.39$;
I (for 16 min.) $= 1.78$;
K (as before) $= 0.87$.

* *Transactions*, Am. Soc. C. E., 1889, Vol. XX, p. 1.

District IX.—Shape not known; area, 132.96 acres; population, 36 per acre; street grades, 1 in 151; sewer grades, 1 in 54 to 1 in 400; time to flow through sewers, 15 min.; time to reach sewers, 8 min.

$L = 4\,000$ ft. (estimated);
$m = 6.6$;
$S = 3.0$ (estimated);
$C = 0.37$;
I (for 23 min.) $= 1.6$;
K (as before) $= 0.87$;

District XVII.—Shape unknown; area, 92.27 acres; population, 35 per acre; street grades, 1 in 240; sewer grades, 1 in 100 to 1 in 350; time to flow through sewers, 16 min.; time to reach sewers, 8 min.

$L = 3\,500$ (estimated);
$m = 4$;
$S = 3.0$ (estimated);
$C = 0.36$ (estimated);
I (for 24 min.) $= 1.6$;
K (as before) $= 0.87$.

Table 1 gives the comparative results of gaugings and computed run-offs.

TABLE 1.

District No.	Highest gauging. Q (cubic feet per second).	Kuichling. Rational method.	Buerger formula.
IV.....	71.3	67.5	51.0
I.....	77.01	92.5	78.5
X.....	21.04	17.4	16.0
IX.....	46.0	78.4	71.0
XVII.....	28.45	53.0	46.5

The comparison in Table 1, of highest gaugings and calculations based on the assumed rainfall curve, is not entirely responsive. A detailed comparison of the special storms is given in Table 2.

For this purpose, it is assumed that K can be determined by the relationship,

$$I = \frac{80\,K}{20 + t} \qquad (12)$$

where I is the intensity for a duration of t minutes,

$$\text{or } K = I(0.25 + 0.0125t) \qquad (13)$$

McMath's St. Louis Observations.*

The information in Mr. McMath's paper is far from being accurate enough to receive much weight. The notes as to overcharge of sewers are not more than observations. It is most difficult to estimate what is intended by the expression "often overcharged." The writer has assumed in the following comparison that a value $K = 1$, corresponding to full discharge in a period of about $1\frac{1}{2}$ years, meets this condition. In all cases, $C = 0.75$, and $m = 15$.

Table 8 gives a comparison of Mr. McMath's records and the calculated run-off.

* *Transactions*, Am. Soc. C. E., 1887, Vol. XVI, p. 179.

* Mr. McMath attributes overcharge to local conditions, rather than to insufficient capacity.

Hill's Chicago Observations.*

Mr. Hill's observations resemble Mr. McMath's in that the record of results is vague, and consists only of a statement of the adequacy or inadequacy of the sewer.

In considering the information given, allowance must be made for a later statement by Mr. Hill,† from which the following is quoted:

"Since the paper under discussion was written, there have been a number of severe rainstorms, that have again demonstrated the inadequacy of many of Chicago's sewers, and have severely tested others that were previously above suspicion. To some extent the opinions of the writer have been modified. On the evening of May 24th there was a downpour aggregating nearly two inches, with a maximum intensity of three inches per hour during a period of fifteen

* *Journal*, Western Society of Engrs., 1902, Vol. VII, p. 425.

† *Loc. cit.*, p. 442.

minutes. The result of this storm was that nearly every deep basement in the city was flooded."

In Table 9, for the purpose of comparison, the run-off as calculated by the Hill method, as outlined in his paper, is given in the column so marked. The coefficient, C, is estimated from the population and the relatively impervious areas noted. The sewer grade, S, is taken as 0.50, and the street grades, m, as 2.0 per 1 000. K is taken as 1 in.

Water-shed Flood Run-off.

Table 10 contains data relating to the maximum flood discharge of streams in the eastern section of the United States, for water-sheds up to 100 sq. miles in area.*

The flood discharges in Table 10 are plotted on the diagram, Fig. 1, by their numbers, together with two curves drawn according to the proposed run-off formulas for values of K of 1.0 and 1.5, respectively.

For comparison, the same assumptions are made throughout.

$L = 300\ \sqrt{A}$, in acres;
$C = 0.15$;
$m = 15$;
$S = 10$;
$K = 1.0$ and 1.50.

Comparison with Other Computations.

Walworth Sewer, Cleveland, Ohio.†—The data and computations used by Mr. W. C. Parmley are taken from Table 2, page 347, of his paper on this sewer. From Fig. 1, on page 351, the highest rainfall, lasting 1 hour, and corresponding to $R = 4$, is taken as $K = 1.1$. From the rainfall records, the indications are that this sewer will never be more than filled. This, of course, is much more liberal than ordinary design, which permits of periodic flooding.

Table 11 gives comparative results of the methods used.

St. Louis Sewers.

Table 12, giving comparative results of the rational method by Mr. W. W. Horner, and the proposed formula, is made up from an article by Mr. Horner.‡

*These are from data by Mr. Kuichling in the New York Barge Canal Report, 1901, p. 852 *et seq.*, and *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 650 *et seq.*

† *Transactions*, Am. Soc. C. E., 1905, Vol. LV, p. 341.

A comparison of Mr. Horner's modern method with Mr. McMath's, as used in 1887 for the same locality, is of interest.

Taking the first item of the table and putting $S = 17$ in the McMath formula, we get, for $C = 0.75$ $Q = 98$

" $C = 0.44$ $Q = 57.5$

Horner $Q = 129.0$

COMPARISON WITH BÜRKLI-ZIEGLER AND MCMATH RESULTS.

Tables 13 and 14 give the comparative computed run-off, in cubic feet per second per acre, for a variation of area, and for a variation in slope, respectively, other elements remaining constant. The constants are chosen so that the same results will be obtained with $A = 100$ and $S = m = 4$.

L (is assumed) $= 400\sqrt{A}$

$C = 0.50$

$K = 1.0$

R (Bürkli-Ziegler) $= 3.58$

R (McMath) $= 3.03$

TABLE 13.

$S = m = 4$.

Tables 13 and 14 are of use only to those who think in terms of either of these two formulas.

Determination of C.—The value of C, which, in the writer's formula, represents the ratio between the run-off and the total rainfall, or, in other words, the ratio of that part of the rainfall not absorbed by or retained on the soil to the total rainfall, will vary much with special local conditions. A study of the nature of the land and its improvements will give some reasonable conclusions as to C.

The existing improvements are not always to be used as a basis of storm-water drain design in a growing community, and for such a

section, not fully developed, some estimate must be made of the probable ratio, C, corresponding to an assumed development at some future time.

A fact, not always fully recognized, is that rain-water falling on a fully impervious surface does not of necessity reach the sewers. This is particularly likely to be the case in a moderately populated district. Rain-water falling on roofs will fully run off from these roofs, but it will often be discharged on lawns and other unprotected surfaces, and the net run-off from these roofs will accordingly be little if any greater than if the rain fell on an undeveloped area of the same imperviousness as the surrounding soil. The same is true of rain-water from paved walks, which are usually bordered by grassed earth of large extent compared with the walks themselves, and the discharge on these unprotected surfaces is largely absorbed. For heavily populated districts, arrangements usually permit of direct discharge of roof and pavement water to the sewers, and no such reduction of run-off need be made.

A very weighty factor in the value of C is the perviousness of the soil, and the corresponding run-off from unprotected areas. The theoretical range will run from 0 for light sandy soils to 1.00 for some rocky or clayey soils. For less unusual conditions, and for the ordinary range of practice, the writer assumes a range of from 5% for soils of sandy nature up to 50% for clay soil. Based on these figures and assumptions, as to the type, number, and size of buildings, areas of streets, walks and their character, the curves of Fig. 2 are derived, in which C is expressed as a function of the population per acre. Table 15 gives a comparison of estimated values of C, based on population, from a number of sources. The coefficient, C, probably does not, in all cases, represent identical conception.

Determination of K.—The determination of K, the rainfall lasting for a period of 60 min., is a relatively simple matter. Records for shorter periods are not always available, but 60-min. rainfalls are often to be had. Plate XIII gives the rate of rainfall for 1 hour duration, in a number of cities, plotted as a function of the average interval in years between such rainfalls. Having a curve of this character for any locality, a selection of the frequency with which the drains are to run full will determine the value of K to be used.

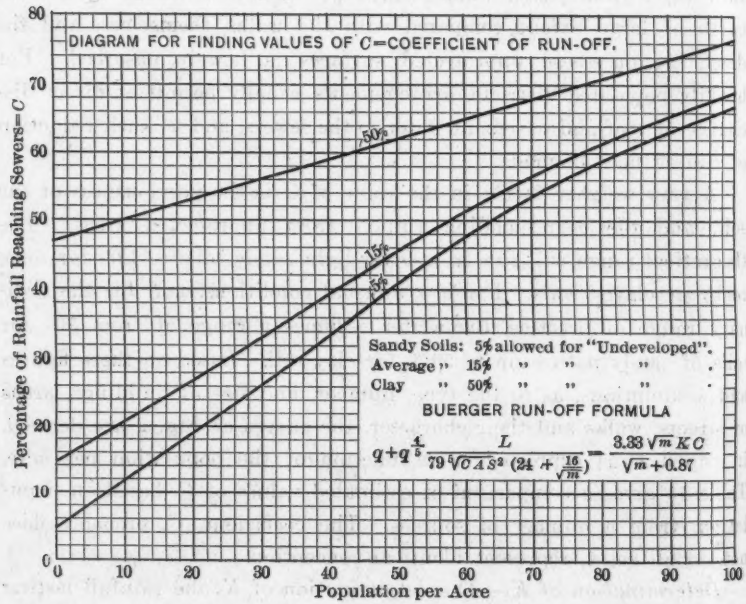

FIG. 2.

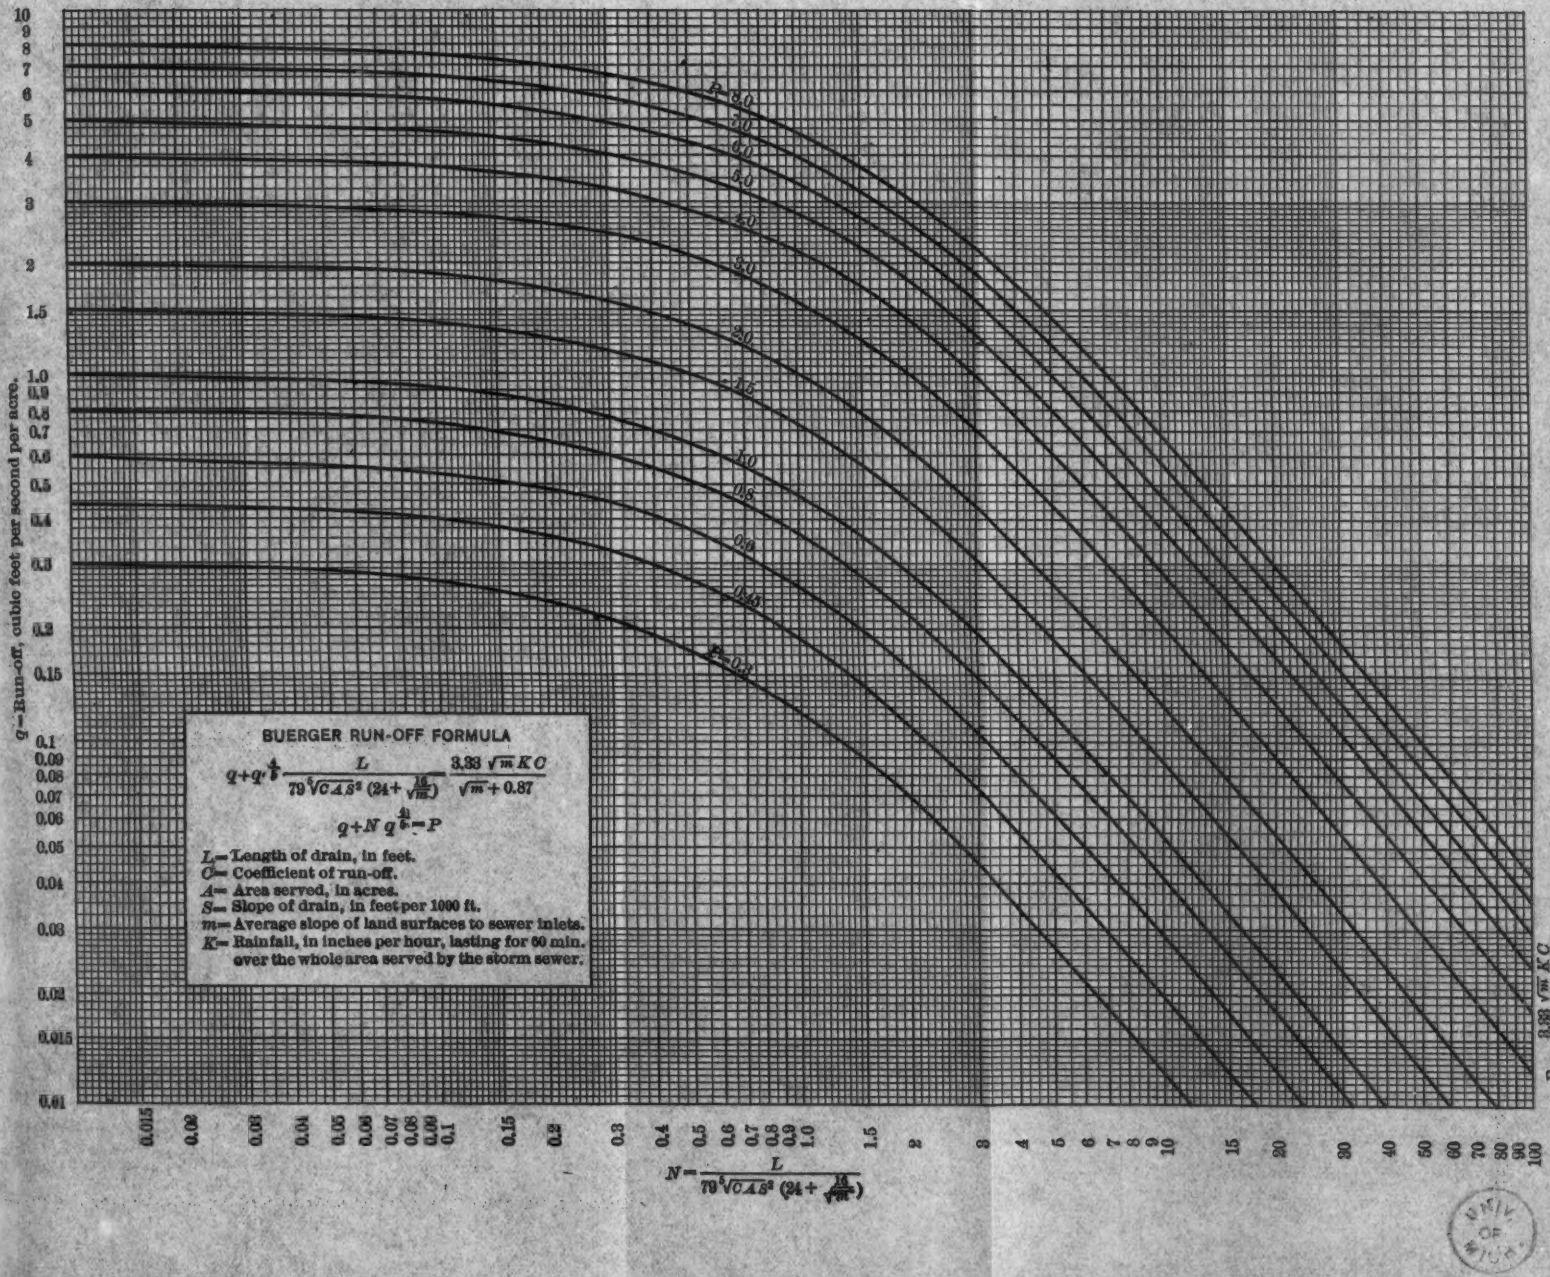
Mr. Imhoff suggests* that an assumption that the sewers will be fully charged by the run-off once every year is a reasonably economical and practical basis, and that longer intervals are not warranted. This would correspond to a value of K ranging from 1 to 1.25 for the Central Eastern States, as shown by Plate XIII.

*Loc. cit., p. 19.



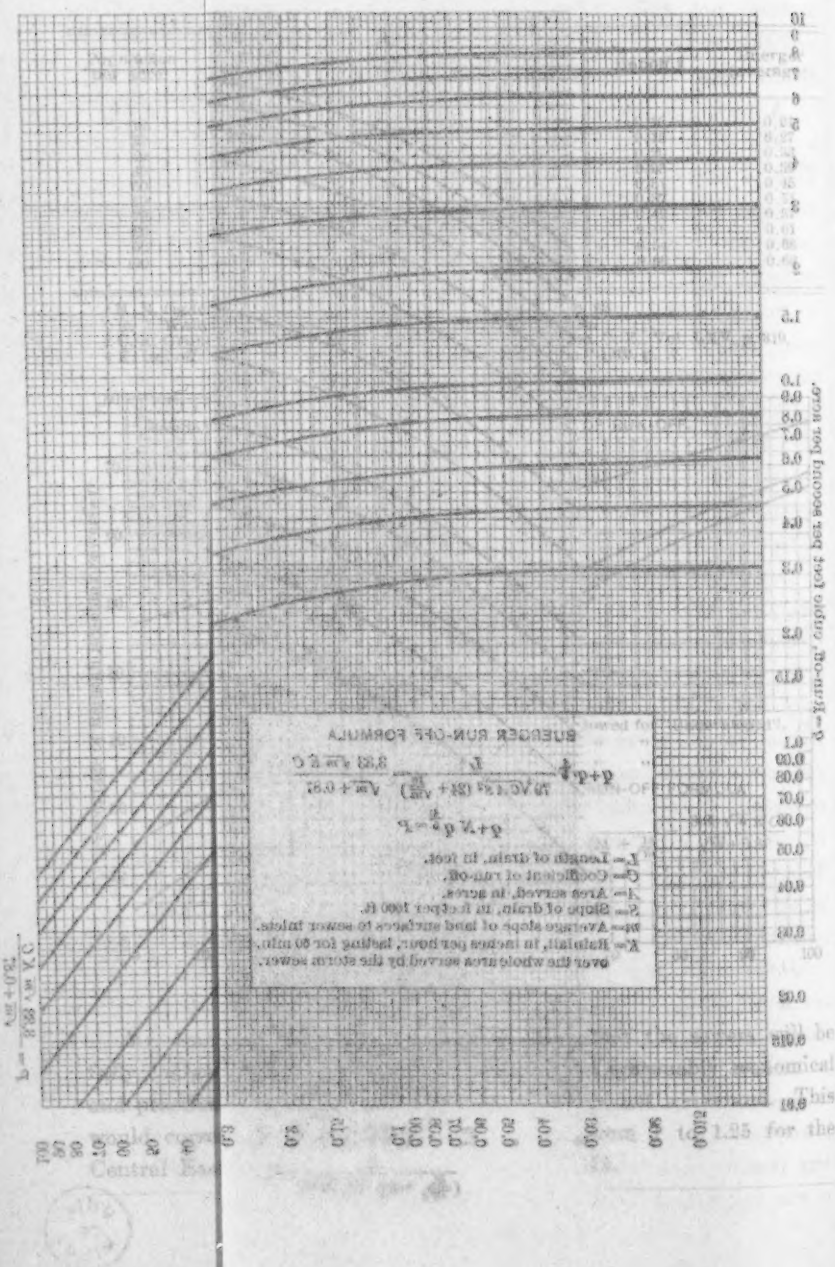
BUERGER RUN-OFF FORMULA

$$q+q\cdot\frac{4}{b}\cdot\frac{L}{79\sqrt[5]{CAS^2}\,(24+\frac{16}{\sqrt{m}})}\cdot\frac{3.33\sqrt{m}\,KC}{\sqrt{m}+0.87}$$

$$q+Nq^{\frac{4}{b}}=P$$

L = Length of drain, in feet.
C = Coefficient of run-off.
A = Area served, in acres.
S = Slope of drain, in feet per 1000 ft.
m = Average slope of land surfaces to sewer inlets.
K = Rainfall, in inches per hour, lasting for 60 min. over the whole area served by the storm sewer.

UNIV. OF MICH.



BUERGER RUN-OFF FORMULA
L = Length of drain, in feet.
C = Coefficient of run-off.
I = Area served, in acres.
S = Slope of drain, in feet per 100 ft.
m = Average slope of land surface to sewer inlets.
K = Rainfall, in inches per hour, lasting for 60 min. over the whole area served by the storm sewer.

The rainfall for which the drains are to provide and the intervals between full flow, must be matters of judgment to be decided according to the relative importance of adequate drainage and first cost.

There is no exact basis on which such a comparison can be made. The amount of damage resulting from a flooding of storm sewers cannot be gauged accurately in advance in dollars and cents. In a few cases the loss resulting from any flooding is so obviously heavy that it immediately appears necessary to provide drains of ample capacity to prevent such flooding under the worst possible conditions. For more ordinary cases, the resultant damage is moderate, and, if not so frequent that the annoyance of flooding must enter as a serious factor, it may be better to submit to such occasional losses than to endure the heavier first cost of drains of larger size. Each case must rest on its own merits, and it is not unreasonable in one city to have an allowed interval between full flow in the drains of from 6 months to 20 years for districts of different character.

Solution of Proposed Formula.—After the selection of values for C and K, which requires some degree of judgment, the work of determining the run-off for any districts of known area, sewer length, sewer grade, surface, and slope becomes entirely mechanical.

To aid in the ready solution of the formula, three diagrams are given. The first of these, Fig. 3, gives the value of P, the right-hand member of the equation. The second diagram, Fig. 4, gives the value of N, the second term of the left-hand member. The third diagram, Plate XIV, gives the values of q, as a function of N and P.

Typical Application of Run-Off Formula.

This calculation is made for one district in Altoona, Pa. A storm curve of maximum intensity is assumed (not here reproduced).

$$C = 0.50$$

$$A = 130 \text{ acres.}$$

Rational Method.—Time of concentration:

1 800 ft. of 24-in. sewer on 80-ft. slope,	1½ min.
1 800 " " 54-in. " " 18-ft. "	2 min.
Time to reach sewers.....	5 min.
	8½ min.

Intensity for 8½ min. duration = 6.2 in. per hour.

$Q = 130 \times 6.2 \times 0.5 = 403$ cu. ft. per sec.

Buerger Formula.—

$L = 3\,600$,

$A = 130$,

$C = 0.50$,

$K = 2.3$ (from rainfall curve),

$m = 49$ (from map),

$S = 40$ (" "),

P, from Fig. 3 $= 3.4$,

N, from Fig. 4 $= 0.158$,

q, from Plate XIV $= 3.0$,

$Q = 130 \times 3.1 = 390$ cu. ft. per sec.

DIAGRAM FOR FINDING VALUES OF THE EXPRESSION,

$$P = \frac{3.33\sqrt{m}\,KC}{\sqrt{m}+0.87}$$

IN THE BUERGER RUN-OFF FORMULA

$$q + q^{\frac{4}{5}} \frac{L}{79\sqrt[5]{CAS^2}\,(24+\frac{16}{\sqrt{m}})} = \frac{3.33\sqrt{m}\,KC}{\sqrt{m}+0.87}$$

C=Coefficient of run-off.
m=Average slope of land surfaces to sewer inlets.
K=Rainfall, in inches per hour, lasting for 60 min.

Find value of m at bottom of diagram. Run up this line as indicated by dotted line to curve. At this point run horizontally to K line then vertically to C line, then run horizontally to P values at right hand side.

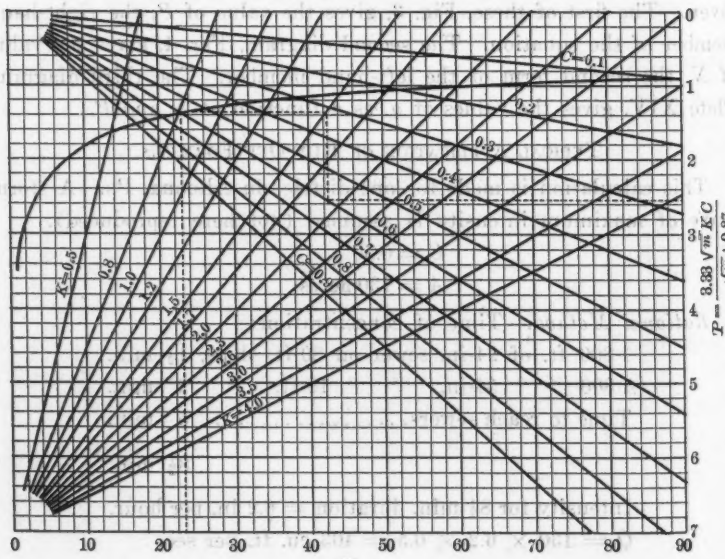


FIG. 3.

DIAGRAM FOR FINDING VALUES OF THE EXPRESSION,

$$N = \frac{L}{79\ \sqrt[5]{C A S^2}\,(24 + \frac{16}{\sqrt{m}})}$$

IN THE BUERGER RUN-OFF FORMULA:

$$q = Q^{\frac{4}{5}} \cdot \frac{L}{79\sqrt[5]{C A S^2}\ (24 + \frac{16}{\sqrt{m}})} = \frac{3.33\sqrt{m}\ KC}{\sqrt{m} + 0.87}$$

L = Length of drain, in feet.
C = Coefficient of run-off.
A = Area served, in acres.
S = Slope of drain, in feet per 1000 ft.
m = Average slope of land surfaces to sewer inlets.

Find value of m at bottom of diagram, run vertically as indicated by dotted line to C curve. At this point run horizontally to S line then vertically to A line then horizontally to L curve, then run up vertically to N values at top of diagram.

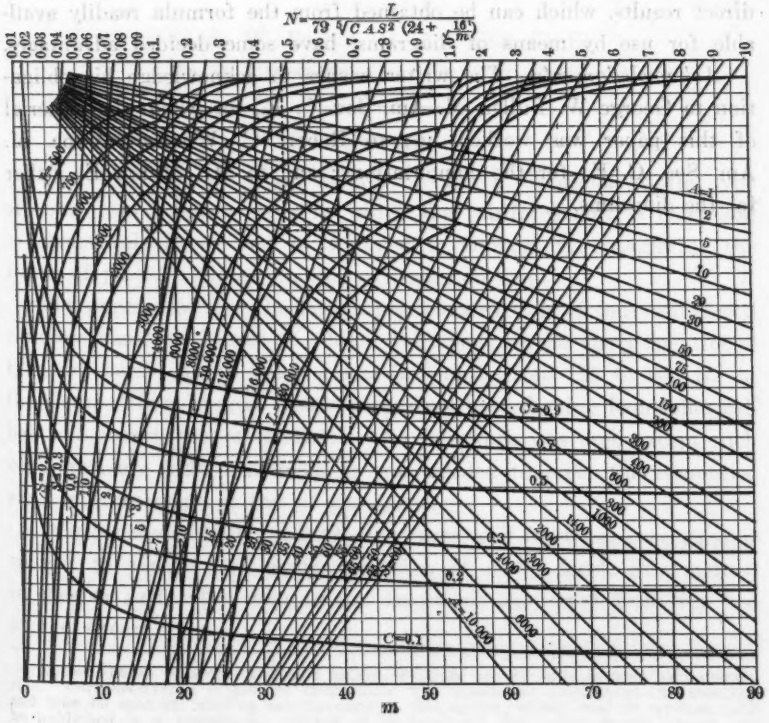

FIG. 4.

The writer has had a large number of computations made on areas varying in imperviousness, extent, length, slope, and with various rates of rainfall, and can state, without qualification or limitation, that the proposed formula gives results in all cases reasonably close to those which will be obtained by the rational method, and that the formula can be taken as an acceptable equivalent.

As compared with the exponential formulas, the results show no relationship except an occasional coincidence at some points under suitable combinations of conditions.

In the writer's judgment the correctness and usefulness of any run-off formula must stand on its corroboration of results obtained by the rational method. The new formula fully meets this condition. Because of its complicated form, there will no doubt be many who will consider a graphical or cut-and-try method more useful. The direct results, which can be obtained from the formula readily available for use by means of diagrams, have some decided advantages.

Acknowledgments.—The writer wishes to acknowledge his obligation to George W. Fuller, M. Am. Soc. C. E., for whom the material of this paper was worked up; to Robert C. Wheeler, Assoc. M. Am. Soc. C. E., for the computations; and to Mr. Myron E. Fuller for the diagrams.

THE DESIGN AND CONSTRUCTION OF FOUR REINFORCED CONCRETE VIADUCTS AT FORT WORTH, TEXAS.

By S. W. Bowen, M. Am. Soc. C. E.

To be Presented October 21st, 1914.

Synopsis.

The object of this paper is to bring out a discussion of the type of reinforced concrete arch in which the reinforcement is composed of structural shapes and is designed to support the weight of the forms of plastic concrete in the arch ring on ribs.

The paper describes the design and construction of four reinforced concrete viaducts, in two of which arch spans of the above mentioned type are used. These spans range in length from 125 to 200 ft., in the clear. Three-hinged, ribbed arches are used, having hemispherical, ball and socket, cast-steel hinges. No falsework was used except such comparatively light timbering as was needed to erect the structural steel reinforcement of two of the spans.

It is concluded that, for high structures, and for those over streams subject to sudden and great variation of water level, this method is cheaper and safer than to use falsework supported from the bed of the stream.

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

The tables give unit and total costs, as well as the cost per linear foot, per square foot of horizontal and vertical projection, and per cubic foot of volume, for each viaduct.

Introduction.

The City of Fort Worth, in Tarrant County, Tex., is traversed by the Trinity River and its branches, the Clear and West Forks. As will be seen by the map, Fig. 1, this stream is very crooked, and cuts the town up badly, necessitating a number of bridges. The city proper lies on the high ground, around which the stream flows. The growth of the residence districts toward the east and west, and the great increase in traffic between the city proper and North Fort Worth, in which the packing houses are located, has recently made necessary the construction of a new viaduct and the reconstruction of three old ones.

The principal feature of this paper is the description of the design and construction of the three-hinged, ribbed-arch spans. In the ribs and rib braces these spans have structural steel reinforcement which is designed to support the weight of the forms and plastic concrete of the ribs and braces during construction. By this means falsework was dispensed with, except such light timbering as was used in erecting some of the structural reinforcement.

These viaducts were built with the proceeds of the sale of bonds issued by the county. The total amount of funds available for construction purposes was about $656 000, exclusive of the accrued interest on the funds in bank.

The firm of Brenneke and Fay, Consulting Engineers, of St. Louis, was selected by the Commissioners' Court to prepare plans and specifications for, and to supervise the construction of, the four viaducts.

The bridges which the viaducts were to replace were old, and too light and narrow to take care of the increasing traffic. The general feeling among the residents of the county was that the new structures should be planned for the future, and be built in such a manner, and of such materials, that they would require the minimum amount of maintenance, and last indefinitely. Therefore, reinforced concrete was selected as the material best suited to the conditions, and was used for all parts of the structures. Creosoted wood block paving

was recommended by the engineers as being light, smooth, and durable, but owing to the high cost of such paving at Fort Worth, vitrified brick was finally selected.

Design.

General Description.—The structures are known, respectively, as the Main Street, West Seventh Street, Samuels Avenue, and East Fourth Street Viaducts. They are mentioned in the order of their cost, the Main Street Viaduct being the largest of the four. The general map, Fig. 1, shows the location of the crossings, and Plate XV shows the four structures drawn to the same scale, so that their relative size can readily be seen.

The widths of roadways and sidewalks are as follows: Main Street, 54-ft. roadway and two 8-ft. sidewalks; West Seventh Street, 43-ft. roadway and two 6-ft. sidewalks; Samuels Avenue and East Fourth Street, 30-ft. roadway and two 5-ft. sidewalks. In each case provision is made for two electric interurban car tracks in the roadway. These tracks are placed in the center of the roadway for the Main and West Seventh Street Viaducts, and at the sides for the two smaller structures. The Main Street Viaduct is the most important of the four, and is on the main artery of travel between the city proper and North Fort Worth. Therefore, it is made wider than the others. The width of roadway is such that four wagons and two street cars can pass abreast. The width of the roadway of the West Seventh Street Viaduct is the same as the width, between curbs, of the street leading up to the crossing. This is ample to accommodate two wagons and two street cars abreast. The two smaller viaducts, being short, and of less importance, as to the volume of traffic to be carried, than the first two named, have roadways of sufficient width to allow only one wagon and two street cars to pass abreast.

From out to out of concrete construction, the length of the Main Street Viaduct is about 1 752 ft., made up of one 225-ft. arch span over the stream, two 175-ft. and one 150-ft. arch spans, one 68 ft. 9-in., two 62 ft. 6-in., seven 50-ft., and two 25-ft. girder spans. The remainder is made up of earth fills enclosed by retaining walls of the semi-gravity type. The West Seventh Street Viaduct is about 1 041 ft. long, consisting of one 137 ft. 6-in. arch span over the stream, and seven 50-ft. girder spans; the remainder consists of retaining

UNIV. OF ILL.

walls. The other two structures each have nine 50-ft. girder spans, and are 450 ft. long, exclusive of the approaches, which consist of earth fills without retaining walls. All the spans are measured from center to center of piers.

In general, ornamentation is confined to the main lines of the structures, and to the use of paneling and mouldings. Railings are simple in outline, and designed with a view to easy construction. Balconies are used at the tops of the main piers at Main and West Seventh Streets, to finish them off properly. The lines of the structures are simple, and there is no applied ornamentation.

Foundation Conditions.—With the exception of a portion of the Main Street and West Seventh Street crossings, rock lies at too great a depth below the surface to be reached, except at excessive cost. At Main Street bed-rock lies at a depth of from 40 to 50 ft. below the ground surface north of the stream. On the south side the rock rises, and crops out at the surface on top of the bluff. Some twenty years ago a landslide occurred on the south bank of the stream. The earth and loose rock overlying bed-rock, slid toward the river, partly wrecking the old bridge. This slide extended for several hundred feet along the stream. It was probably caused by water seeping down from the bluff and softening the material in the hillside.

The material on the south side of the river consists of loam and clay interspersed with loose rock and boulders brought down by the slide. This material is underlaid with ledges of rock, varying in thickness from 6 in. up, with thin layers of hard clay or shale between. The layers are horizontal, and increase in thickness with the depth. The material on the north bank, to a depth of 10 or 12 ft., consists of a black, sticky, clay-like substance, which has the property of remaining very hard when moist and not exposed to the air, but which disintegrates when exposed to dry air for a few days. Under this surface material there is a very dense yellow clay, underlaid with sand. This sand increases in coarseness with the depth, and merges into gravel near bed-rock. The surface material was tested at a depth of 8 ft., and sustained a load of 3.3 tons per sq. ft. without appreciable settlement. The material north of the stream at Main Street is fairly typical of that at the other crossings.

River Conditions.—The Trinity River, though normally a small stream, hardly larger than a creek, is subject to sudden freshets, and

carries large quantities of drift. The banks are steep and the run-off is rapid. As an example of the rapidity of the rises, may be mentioned a flood that occurred during the summer of 1912, before work started, and another in September of 1913, while work was under way. During the first mentioned freshet a rise of 23 ft. occurred in 24 hours. This rise was gradual compared with the last mentioned flood, where the rise, measured at West Seventh Street, amounted to a total of 16 ft. in about 1½ hours. The first 14 ft. of this rise took place in about 1 hour. Such floods as these are not at all unusual, and make work in the bed of the stream decidedly hazardous.

Selection of Type of Structure.—Because of the conditions mentioned above, it was necessary to adopt a type of structure that would not be injured by such slight unequal settlement as, under the circumstances, might be expected to occur. It was also thought advisable to use, at least for the arch spans, a method of construction that would not require falsework in the stream.

After a careful consideration of various types, it was decided to use, for the main spans of the two larger viaducts, three-hinged, ribbed arches, with structural steel reinforcement designed to support the weight of the forms and plastic concrete of the ribs and braces during construction. For the approach spans and for the river spans of the smaller viaducts, girder spans were adopted.

The three-hinged arch was selected because it would not be strained by unequal settlement, because the stresses are statically determinate, and temperature stresses are eliminated. Ribbed construction was adopted as being light and best adapted to the use of hinges, and also because no water-proofing would be required. Structural reinforcement for the ribs and braces was used in order to dispense with falsework, as far as possible.

Preliminary Design.—Before beginning the actual designing, a considerable amount of preliminary work was done in order to determine the most economical type of structure for various heights, and also to determine the economical span lengths for each type. Three types were considered, as follows: earth fills enclosed by semi-gravity retaining walls, girder spans, and arch spans.

In this preliminary work sufficient designing and laying out was done to enable the various quantities to be determined with sufficient accuracy for the purpose in view. These quantities were multiplied

by estimated unit prices, and the cost per linear foot of structure, of each type, for various heights and span lengths, was obtained. These results were then plotted, and the economical span lengths were determined, as well as the points at which it was theoretically economical to change from one type of construction to another. The information obtained from the plots was followed as closely as circumstances would permit. In some cases, however, the physical conditions encountered determined both the span lengths and the type of structure. For example, at Main Street, arch spans were used over the levee, and between the south abutment and Pier No. 1. Girder spans would have been cheaper at these points, if the height only were considered. It was not permissible to place piers in the levee, and a long span had to be used. It was not thought advisable to divide the span between the South Abutment and Pier No. 1, on account of the possibility of a recurrence of the slides mentioned previously; in other words, the fewer piers on the south bank of the stream at this point, the better. Consequently, arch spans were used for these portions of the crossing.

Girder spans would have been cheaper than the arch at West Seventh Street, but, as this structure is near one of the city parks, and in a high-class residence district, an arch was used over the stream, for esthetic reasons.

Girder spans were used throughout for the Samuels Avenue and East Fourth Street crossings, for the sake of economy, and to afford the maximum clear opening with minimum height. This required the use of falsework in the stream. This was undesirable, but it was considered that as in this case the girder spans were considerably cheaper than self-supporting arches, and that as these crossings were situated so that the force of the current at flood stage was much less than at the other crossings, girder spans would answer the purpose.

The selection of the three-hinged ribbed arch with forms supported from the reinforcement, was governed principally by the character of the foundations, and by the erratic behavior of the stream. However, at Main Street, estimates were made of the cost of this construction as compared with that of a three-hinged ribbed arch supported on falsework in the usual manner. In making this comparison, the cost of the falsework and the rib reinforcement required for this scheme was compared with that of the rib reinforcement of the arches

as built. The hinges, and such portions of the rib forms as were common to both schemes, were not included in the estimate.

It was found that the structure on falsework would have cost slightly less than as built. This was caused by the fact that Spans *A*, *C*, and *D* are too low for economy with the self-supporting type of construction. Span *B*, however, is high enough to make this type economical. It was decided to use the self-supporting type for all spans, because of the danger from floods, the unstable character of the soil under Span *A*, and in order to avoid the troubles due to settlement of the falsework.

The selection of the self-supporting type was amply justified by events which will be mentioned later, under the head of "Construction."

General Layouts.—After the preliminary designing had been finished, and the data obtained had been arranged for use, the work of preparing the general plans was started. The Main Street structure is typical of the work, and will be used as an example throughout the remainder of this paper.

The general plan of this crossing, Plate XVI, shows its location with reference to the principal streets and public buildings. It will be seen that a direct approach to the south end of the structure was prevented by the Court House and Jail buildings, which block Main Street at this point. It was desirable, therefore, to make the south approach a double one. One branch, carrying north-bound traffic, connects with Commerce Street, and the south-bound traffic is accommodated by the other branch, which connects with Houston Street. Sufficient property has been acquired to allow the street corners to be rounded off, so that the approaches may follow easy curves.

Curved retaining walls and railings are being constructed south of the south abutment, where the viaduct proper ends. It is expected that the block now occupied by the Jail and other buildings, will be cleared by the City, and will be parked to form a pleasing approach to the crossing.

The general elevation was laid out to fit the conditions, keeping in mind the data obtained from the preliminary designs. It will be seen by referring to this general elevation, Plate XVII, that a symmetrical structure was not possible, owing to the contour of the ground.

Structural Features.—Before going into the matters of loading, unit stresses, and methods of design, it may be well to give a descrip-

tion of some of the features of the Main Street Viaduct, in order to show the character of the construction, and to make clearer some of the problems involved in the design.

As shown by the plans, the deck consists of slabs carried on longitudinal stringers, which connect to floor-beams. These floor-beams are in turn carried by the four main longitudinal girders of the girder spans, or by the spandrel posts, which rest on the four ribs of the arch spans. The sidewalks are carried on cantilever extensions of the floor-beams outside of the outer girders or ribs. It will be noticed that, for the girder spans, such stringers as would come close to the girders are omitted, and their place is supplied by the cantilevered top flanges of the main girders. Those cantilevered top flanges also provide the necessary compressive area for the girders.

Two ribs or main girders would have been more desirable in some respects than four, as this arrangement would have done away with the continuous girder action of the floor-beams, and made the reactions on the girders and ribs statically determinate. The heavy concentrated loading and the width of the roadway, however, would have made the floor system extremely heavy. Therefore the four-rib arrangement was adopted for this crossing. At West Seventh Street, three ribs were used, and two lines of main girders for the other two structures.

The same length of floor system panels was adopted for all the structures. This made the design of the stringers practically uniform throughout. The length used was 12 ft. 6 in. from center to center of floor-beams, which gave stringers of reasonable size and brought the loads on the girders and arch ribs at reasonably short intervals. The floor-beams are of uniform thickness throughout, which thickness, 17 in., is the same as that of the spandrel posts. The posts are purposely made thinnest in the direction of the axis of the structure, so that the bending caused by the changes in the length of the deck due to temperature, will not over-stress them.

Expansion joints are provided in the girder spans at each pier, and in the deck of the arch spans, at the crown, and at each pier. The main girders slide on top of the small piers, and the stringers slide in recesses or pockets in the floor-beams. All expansion joints are packed with tar-paper and asphalt to form a closed but compressible joint, and all main girder joints are masked by pilasters. Planed steel, bed-

and bearing-plates are used under the expansion end of each girder and stringer. These plates have anchorage angles riveted to them, and are further anchored with bent anchor-bolts passing through holes in these angles. The sliding members, and those on which the sliding members rest, are also reinforced at these bearing points with loops of steel, to provide for the shearing stresses which result from the friction of the plates on each other. In order to reduce this friction as much as practicable, the bed- and bearing-plates are planed in the direction of movement, and the sliding surfaces in contact are heavily coated with tallow. U-shaped copper plates, filled with asphalt, are used in the roadway slabs to close the opening. Similar plates placed in the reversed position to those in the roadway slabs, and with the asphalt filling omitted, are used in the sidewalk slabs and curbs. These copper plates are used at each expansion joint in the structure.

The arch ribs are braced together at the foot of each spandrel post by transverse braces, which are of the same width as the spandrel posts and floor-beams, and as deep as the ribs will allow. These braces are placed in vertical planes.

The arch ribs are of uniform thickness, but vary in depth, decreasing regularly from the haunch toward the crown. This is contrary to the theoretical shape of a three-hinged rib, which should be deepest at about the quarter point of the span, and diminish in depth toward the haunch and crown. This departure from the theoretical shape was made for the sake of appearance only. As the hinges are concealed in the finished rib, it was considered that the ribs would look best if made to follow the lines of a hingeless rib.

Each hinge consists of two steel castings, having ball and socket joints. At the haunches one of these castings is built into the pier, and the other is bolted to the structural rib reinforcement, as are also the castings forming the crown hinge.

All the piers for the arch spans are of considerable width in order to resist overturning forces and to give the appearance of massiveness required by the long spans. They are hollowed out as much as is consistent with strength and economy of forms, in order to reduce their weight and to save material.

The small piers supporting the girder spans consist of four square shafts, battered on the four faces. These shafts rest on a common base and are connected at the top by a cap and diaphragm of T-section.

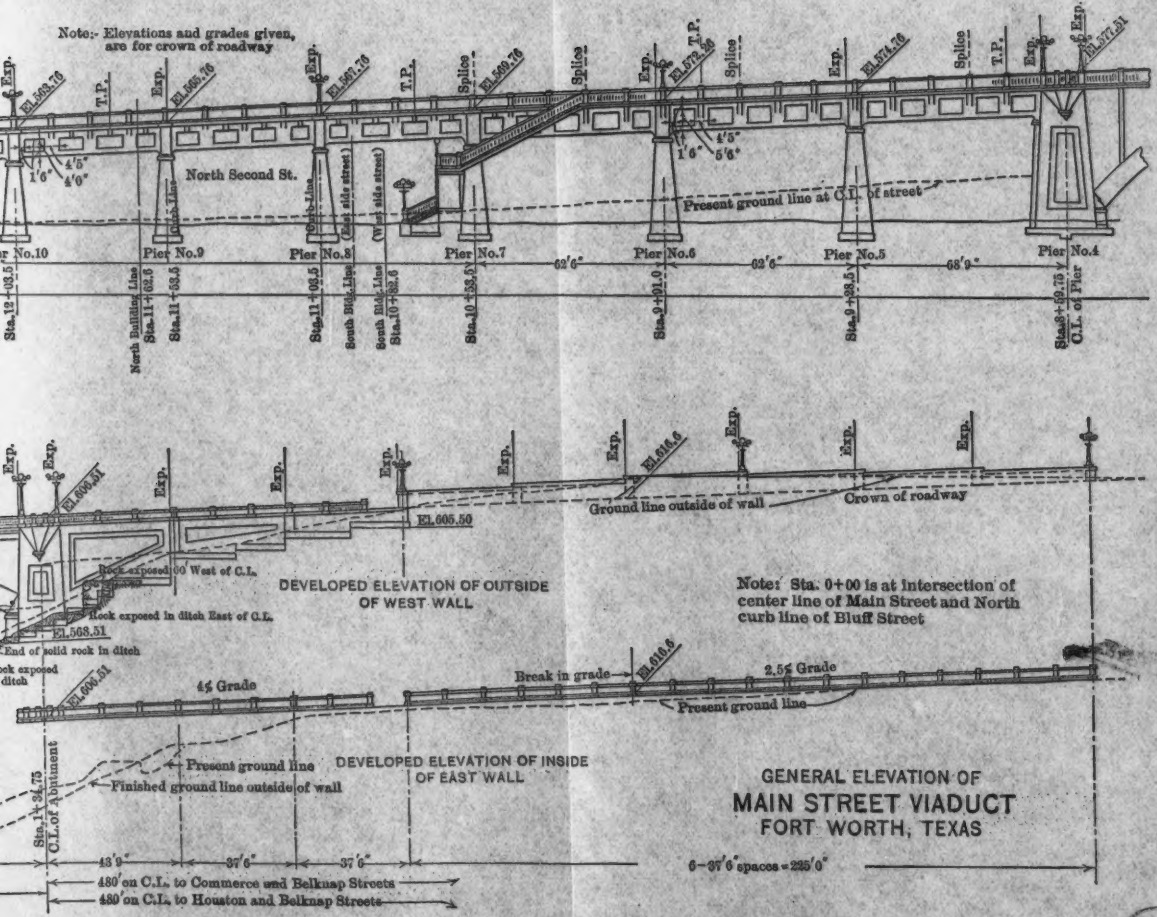
BOWEN ON
REINFORCED CONCRETE VIADUCTS.



GENERAL ELEVATION OF
MAIN STREET VIADUCT
FORT WORTH, TEXAS

UNIV. OF MICH.

The retaining walls are of the semi-gravity type. The toe of the section is reinforced for bending stresses, and the reinforcement extends high enough up the back of the wall to relieve the concrete of undue tensile stresses. Expansion joints are provided at intervals of 37 ft. 6 in., and pilasters are used at these points to mask the joints. The walls have a small coping and are paneled to relieve the appearance of flatness.

The South Abutment is founded on rock, as is also Pier No. 1, which is on the south bank of the stream. Pier No. 2, on the north bank, is supported on a spread foundation, with a portion of the load carried on timber piles. All other piers and walls are carried on spread footings, resting on the strata previously referred to, at depths ranging from 4 to 18 ft. below the finished ground surface.

Railings, and the stairways leading down to the street level at North Second Street, are of reinforced concrete, cast in place, except the railing panels and hand-rails, which were cast in moulds and erected.

The stairways, with the exception of the steps leading to the lower landing, are supported entirely from the piers and girders by structural steel cantilever beams encased in concrete. This method was adopted, instead of supporting partly on the piers and girders and partly on independent posts and foundations, in order to avoid the danger of damage due to unequal settlement. The lower steps were built on independent foundations, with a sliding joint between the steps and the remainder of the stairway, to take care of unequal settlement.

Provision is made for carrying electric wires and small pipes under the sidewalks, with ducts leading into the railing posts and up to the lighting fixtures.

In order to reduce the dead weight of the deck as much as possible, the usual ballasted track construction was dispensed with. Anchor-bolts were set into the slab over the stringers, and the rails were secured to these bolts with cast-steel clips. Steel bearing-plates were provided under the rails at each pair of bolts, which occurred at intervals of 27 in. The rails were lined and brought to proper level, with eccentric washers and shim plates. A fiber pad, ½ in. thick, was placed between the rail and the bearing-plate, as a shock absorber. This method of securing the rails is indicated on the plans.

The reinforcement of the arch ribs and braces consists of medium-steel structural shapes, supplemented by reinforcing bars. Structural

shapes are also used for the main supports of the stairways. All other reinforcement consists of square twisted bars, of high elastic limit. These were substituted for the round, mechanical-bond bars called for on the plans, and were made equivalent in cross-section to the round bars which they replaced. All bars, except some of the large sizes, were rolled from the heads of rails, and were hot-twisted. Cold-twisted bars, from medium-steel billet stock, were used for the large sizes, on account of the difficulty of getting rail heads of sufficient volume for this purpose. Tests of the two classes of material showed that they were practically equal in quality.

As shown on the plans, the rib reinforcement consists of curved lattice girders, to the ends of which are bolted the cast-steel hinges. The chords of these girders are made up of four angles arranged in the shape of a cross. All web members are made up of two angles. Three of these steel girders are used in each inner, and two in each outer, rib of each span. The individual steel girders are laced together in the plane of the top and bottom chords, and are also connected by transverse frames, in vertical planes, under each post. The transverse braces connecting the four ribs are reinforced by lattice girders which connect to the rib reinforcement. No reaming or painting is called for. The hinge castings are bolted to the steel ribs, and all other connections, both shop and field, are riveted.

At each upper panel point of the steel ribs, clip angles were provided, to which were secured the transverse timber beams, from which the rib forms were supported. The method of supporting these forms is indicated on the plan showing the arch rib reinforcement.

A system of lateral rods, for use during erection, was provided in the plane of each chord of the ribs. These rods were used to line up the steelwork accurately, and to hold it in line while the ribs were being concreted. The rods were not removed until after the completion of the work. The transverse braces, mentioned previously, are also reinforced in each face with continuous bars, the function of which is to resist bending in the braces due to transverse forces.

In addition to the steel reinforcement required to resist the calculated stresses in the members, a certain quantity of steel is used to prevent the formation of shrinkage, settlement, and temperature cracks. This steel is used in the exterior faces of thin walls, in a longitudinal direction in the slabs, and to reinforce the corners where

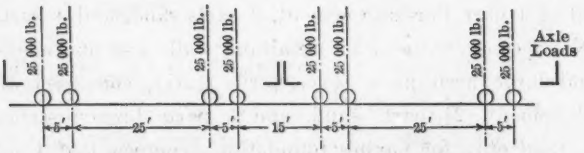
two walls join. All braces, ribs, and posts are wrapped with heavy wire closely spaced, to which the longitudinal steel is secured.

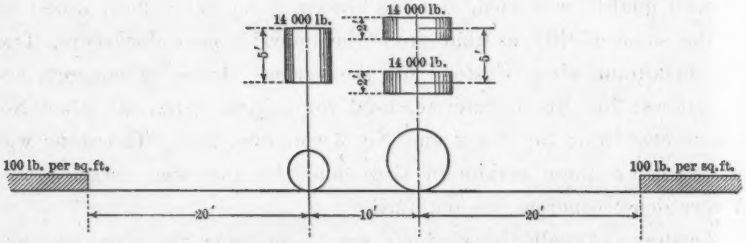
The concrete used in the construction of the viaducts is of three classes: No. 1 concrete, used for floor systems, girders, arch ribs, braces, spandrel posts, railings, stairs, and rib seats of large piers, composed of 1 part Portland cement, 2 parts sand, and 4 parts broken stone; No. 2 concrete, used for retaining walls and abutments, girder piers, and large arch piers (except rib seats), composed of 1 part Portland cement, 2½ parts sand, and 5 parts broken stone; No. 3 concrete, used only for paving foundations, composed of 1 part Portland cement, 3 parts sand, and 6 parts broken stone. A local sand of good quality was used, and the broken stone was a hard limestone of the same quality as that from the quarries near Jacksboro, Tex. The maximum sizes of stone for the various classes of concrete are as follows: for No. 1 concrete, used for railing, ¾-in., all other No. 1 concrete, 1-in.; for No. 2 and No. 3 concrete, 2-in. The stone was graded below these maximum sizes, and the dust was screened out. A very dense concrete was obtained.

Loading.—As all the viaducts are in or near the city, and are likely to carry the same class of traffic eventually, the same live loading was used throughout. The loading data are shown by Figs. 4 to 7, inclusive. The 50-ton electric cars and the 21-ton road roller shown thereon, were used for the members of the floor system, together with a uniform load of 100 lb. per sq. ft. on the sidewalks and remaining roadway surface. For maximum stresses in the floor-beams, the sidewalks were assumed to be unloaded. The arch ribs and the main longitudinal girders were designed for the foregoing car loading, together with 100 lb. per sq. ft. on the sidewalks and the remainder of the roadway. The road roller was also considered in connection with the car loading, with the foregoing uniform live load on the sidewalks and the remainder of the roadway. A load of 200 lb. per lin. ft. of each sidewalk was also used, in order to provide for the weight of pipes and conduits that might be carried in the spaces provided for them under the sidewalks. Pier footings were designed for a uniform load per linear foot of each car track, as given on Fig. 5, together with a uniform load of 100 lb. per sq. ft. on the sidewalks and the remaining roadway surface.

Impact was allowed for according to the following formula: $I = \frac{100\,S}{L + 300}$, where I is the impact to be added to the live load stress, S is the calculated maximum live load stress, and L is the loaded length, in feet, that produces the maximum stress in the member.



Two 50-Ton Electric Cars as above on each Track
Area covered by 4 cars as above 20'x 100'



One 21-Ton Road Roller as above on any part of Roadway
Width covered by Roller 10'

The car and roller given above, together with 100 lb. per sq. ft. on sidewalks and remainder of roadway, to be used in design of floor system, main longitudinal girders, and arch ribs. For Piers and footings, use 100 lb. per sq. ft. of sidewalks and Roadway and uniform track loading as per diagram, except Case II in design of arch Piers, where wheel loads are to be used to give maximum thrusts.

IMPACT

On sidewalks	none
Road Roller	25%
Other roadway loads and track loads	$I = S\frac{100}{L+300}$

where I = Impact to be added to the Live Load Stress.
S = Calculated maximum Live Load Stress.
L = Loaded Length, in feet, which produces maximum stress in the member.
No impact to be used in design of Piers and footings.

FIG. 4.

This impact allowance is one-third of that required by the original formula, submitted by the American Railway Engineering and Maintenance of Way Association, for impact on steel railway bridges, and was arbitrarily assumed. This formula was used only for car and

uniform roadway loads. Stresses produced by the road roller, which is a slowly moving load, were increased by 25% in all cases. No addition was made for impact to the stresses produced by the uniform sidewalk loading, as it was considered that when this sidewalk load was a maximum, that is, due to a closely packed crowd of people, it neces-

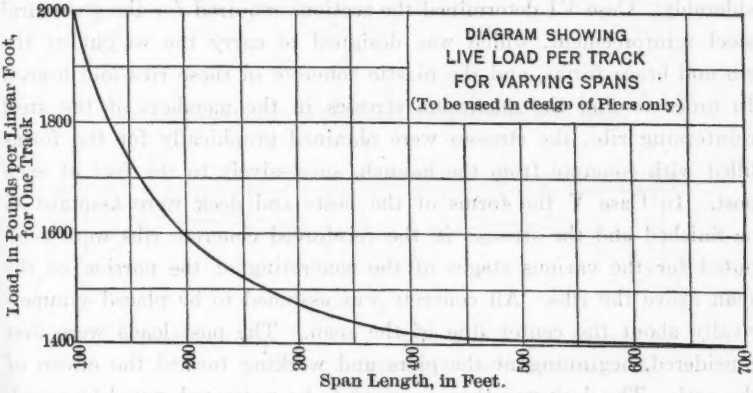


FIG. 5.

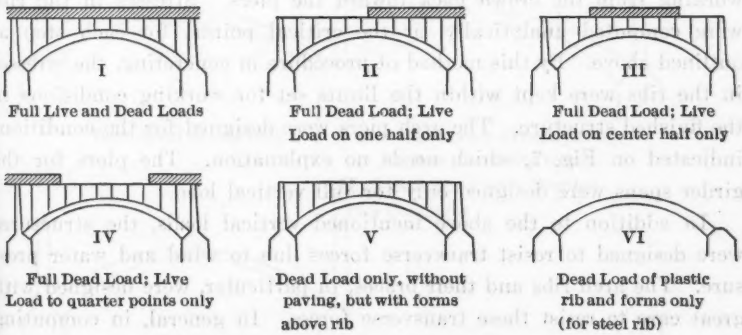

LOADING TO BE USED IN DESIGN OF ARCH RIBS

Note: In all cases where Live Load is called for, Wheel Concentrations shall be used and Allowance included for Impact

FIG. 6.

sarily would be nearly quiescent. The live loads for the piers were not increased for impact, as it was believed that the impact would be absorbed before reaching the footings.

The various conditions of loading for which the arch ribs were designed, are indicated on Fig. 6. Cases I to IV require no explana-

tion, except to say that they served to produce maximum stresses in the ribs of all spans except those of the unsymmetrical arch, Span *A*. On account of this lack of symmetry, these cases were elaborated on, in order to be sure that the maximum stresses had been found. Cases V and VI are construction conditions, and were elaborated on considerably. Case VI determined the sections required for the structural steel reinforcement, which was designed to carry the weight of the rib and brace forms, and the plastic concrete in these ribs and braces. In order to find the maximum stresses in the members of the steel reinforcing ribs, the stresses were obtained graphically for the forms filled with concrete from the haunch, successively to the foot of each post. In Case V the forms of the posts and deck were assumed to be finished and the stresses in the reinforced concrete ribs were computed for the various stages of the concreting of the portion of the span above the ribs. All concrete was assumed to be placed symmetrically about the center line of the span. The post loads were first considered, beginning at the piers and working toward the crown of the arch. The deck was then assumed to be concreted, panel by panel, working from the crown back toward the piers. Stresses in the ribs were computed analytically, at the critical points, for each step as outlined above. By this method of procedure in concreting, the stresses in the ribs were kept within the limits set for working conditions in the finished structure. The arch piers were designed for the conditions indicated on Fig. 7, which needs no explanation. The piers for the girder spans were designed only for full vertical load.

In addition to the above mentioned vertical loads, the structures were designed to resist transverse forces due to wind and water pressure. The arch ribs and their braces, in particular, were designed with great care to resist these transverse forces. In general, in computing these transverse forces, the water line was assumed to be at the top of the levee. Below this line the pressure due to the current was taken at 200 lb. per sq. ft. of vertical projection of each arch rib and spandrel post. Above this line the wind pressure was assumed at 30 lb. per sq. ft. of vertical projection of the structure, up to a line 10 ft. above the top of the roadway. The force assumed for the current corresponds, according to the formula used, to a velocity of about 8 or 9 miles per hour, which is probably not far from the actual velocity at flood stage.

At the West Seventh Street crossing, where the rise of the arch is small, and the high-water line comes well up on the arch rib, and where considerable drift is carried by the stream, more severe conditions

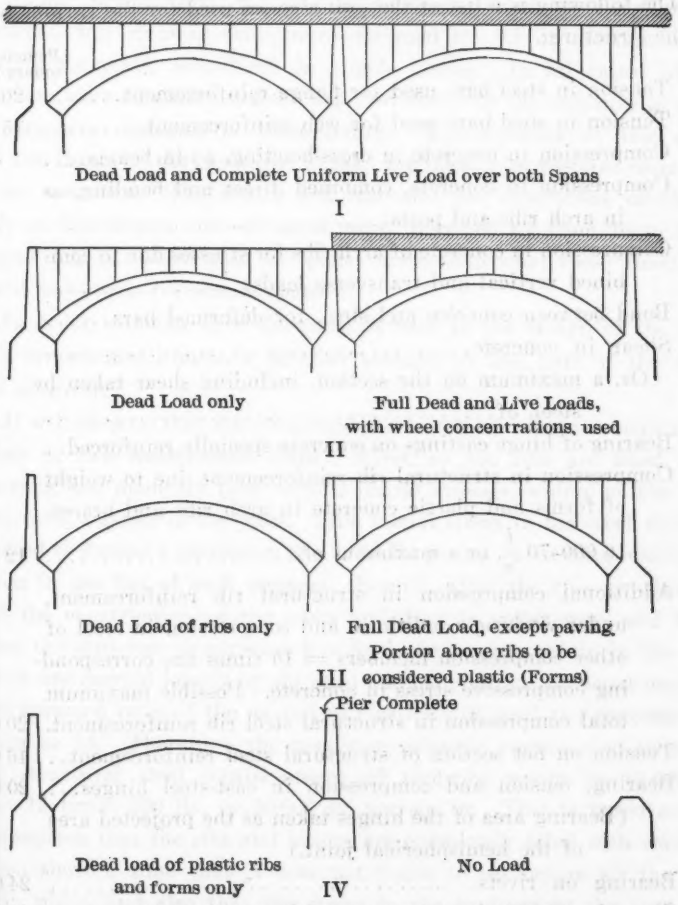

FIG. 7.

of transverse loading than those mentioned above, were assumed. In this case the water line was taken at the top of the arch rib, at the crown, in order to allow for the possibility of drift collecting against the span.

Specifications.—With certain modifications, in regard to unit stresses, "Watson's Specifications for Reinforced Concrete Bridges" were used.

The following is a list of the unit stresses used for the various parts of the structure:

	Pounds per square inch.
Tension in steel bars used for flange reinforcement	20 000
Tension in steel bars used for web reinforcement	15 000
Compression in concrete in cross-bending, as in beams	750
Compression in concrete, combined direct and bending, as in arch ribs and posts	500
Compression in concrete of arch ribs for stresses due to combined vertical and transverse loads	650
Bond between concrete and steel, for deformed bars	120
Shear in concrete	60
Or, a maximum on the section, including shear taken by steel, of	150
Bearing of hinge castings on concrete specially reinforced	800
Compression in structural rib reinforcement due to weight of forms and plastic concrete in arch ribs and braces, $16\,000-70\,\frac{l}{r}$, or a maximum of	12 500
Additional compression in structural rib reinforcement, under working conditions, and compression in steel of other compression members = 15 times the corresponding compressive stress in concrete. Possible maximum total compression in structural steel rib reinforcement.	20 000
Tension on net section of structural steel reinforcement	16 000
Bearing, tension and compression in cast-steel hinges	20 000
(Bearing area of the hinges taken as the projected area of the hemispherical joint.)	
Bearing on rivets	24 000
Shear in cast steel	10 000
Shear on rivets	12 000
	Pounds per square foot.
Bearing on soil at depth of 6 ft. below finished surface	5 000
For each 1 ft. increase in depth, more than 6 ft., add	100
	Pounds.
Load on each timber pile	20 000

Methods of Design.—There is nothing unusual in the design of the structures, with the exception of the methods of designing the arch ribs and braces. Briefly, sidewalk slabs and main girders were designed as simple beams, and continuous members, such as floor-beams, stringers, and roadway slabs, were designed for 0.8 of the maximum positive moments, considered as simple beams. In all cases, where members were continuous, steel was provided over the supports to take the negative moments at these points. The quantity of this steel was two-thirds of that required to take the maximum positive moments in the members. The shears and reactions for continuous members, such as floor-beams and stringers, were increased by from 10 to 25% (depending on the number of spans) more than what these functions would have been for simple spans.

In order to make clear the methods used in the design of the arch ribs, braces, and hinges, a detailed account of this part of the work will be given.

It will be seen that the structural steel arch rib reinforcement takes stress in two independent steps: First, as the ribs are filled with concrete, the members take certain initial stresses, which, as the concrete sets, remain in the steel. This initial stress in the steel was not allowed to exceed a maximum of 12 500 lb. per sq. in. in compression, as given in the list of unit stresses. Second, after the ribs are finished and the construction of the posts and deck is under way, and later, when the structure is carrying live load, stresses are set up in the ribs, which are carried jointly by the steel and concrete in the usual manner. The assumed ratio of the moduli of elasticity of steel and concrete was taken as 15. Therefore, the maximum possible compressive stress in the structural steel reinforcement of the ribs would be 12 500 lb. plus 15 times 500 lb., or 20 000 lb. per sq. in. This is based on the assumption that the ribs and braces are completely filled with concrete in so short a time that it does not begin to set before all the load is in place, and also that the stress in the concrete at the center of gravity of the steel chord is 500 lb. per sq. in. As a matter of fact, the ribs were concreted in sections, and the braces were not concreted until the concrete in the ribs had set for several days. Consequently, the initial compression in the structural reinforcement was much less than that mentioned above. The center of gravity of the steel chords is some distance in from the face of the concrete, so that the concrete

stress at this point, and therefore the stress in the steel, is lower than that assumed. The actual maximum compression in the structural reinforcement is about 16 000 lb. per sq. in.

The lines of pressure for the ribs were worked out graphically for the various positions of the live load, combined with dead load, and for the various stages in the construction of the deck. In order to allow for the weight of the ribs themselves, their dimensions were first assumed, and later were revised where necessary. The neutral axes of the ribs were drawn midway between the extreme pressure lines. This made the neutral axis of the rib a constructive curve, approximating a parabola with its vertex at the crown of the arch. The axis as drawn followed closely the pressure line for full dead and live load. The inner and outer ribs were made of the same vertical dimensions, but of different thickness.

The next step was to find the stresses in the reinforced concrete rib for the various stages in the construction of the deck, and for the dead and live load, under working conditions in the finished structure. The quantity of steel required at each point to keep the extreme fiber stress in the concrete down to 500 lb. per sq. in. for the worst condition, was then computed. The required area of steel in either face of the rib at any point was not allowed to exceed 2.5% of the total cross-sectional area of the rib. Where, on first trial, the required quantity of steel exceeded the above maximum, a re-design was made, using a rib of larger cross-section.

As mentioned under the head of "Loading," the stresses in the structural steel ribs were found graphically for the various positions of load during the concreting of the ribs and braces, using the rib having the dimensions which had been determined as just described. The sections of the structural steel reinforcement were then determined. This structural steel reinforcement, though designed to carry the ribs and braces during their construction, also forms part of the reinforcement of the finished rib, as previously mentioned. Where the required area of steel in the finished rib exceeded that supplied by the structural reinforcement, the deficiency was made up by the addition of reinforcing bars. These bars do not run the full length of the ribs, but stop off where they are not needed. It will be noticed that these bars take little, if any, initial stress, such as is taken by the structural reinforcement. Additional bars are placed in the

UNIV. OF MICH.

sides of the ribs, running full length. These bars help to resist transverse bending stresses, and to prevent surface cracks from appearing.

The transverse forces of wind and water pressure, mentioned previously, were assumed to be resisted wholly by the ribs and braces acting as a series of portals, in the same manner as the columns and girders of an office building act to resist wind pressure. The deck was not given credit for any resisting power, because of the presence of the expansion joints over the haunch and crown of the span.

Points of inflection were assumed in the braces, midway between each pair of ribs, and in the ribs, midway between the braces. The ribs being hinged at the haunches and crown, were computed as being free to move at these points. Bars were provided at the haunches, however, anchoring the ribs to the piers, and at the crown, anchoring the two halves of the rib together. These bars were placed in the plane of the neutral axis of the rib, and tended to resist transverse, but not vertical movement, of the ribs. The stresses in the ribs and braces were computed at each section, for the moments, shears, and direct thrusts in the members. The maximum stresses at each point in the ribs, due to transverse forces, were combined with the maximum stresses due to the vertical loads, and the ribs were proportioned accordingly.

The design of the hinges naturally received considerable attention. At first, a hinge was studied which consisted of two castings, having semi-cylindrical bearings, and a pin. This type has a number of advantages, but was finally abandoned on account of the difficulty of setting the hinges on the piers with sufficient accuracy. Unless the axes of the pins are placed exactly at right angles to the vertical plane through the longitudinal axis of the rib, eccentric stresses will result in the rib, which may be too large for safety. It was finally decided to use hinges composed of two ribbed steel castings, having a hemispherical ball and socket joint, as shown on the plans. This joint was machined, and, by allowing movement in all directions, made great accuracy in setting the castings unnecessary. This joint also made it possible to adjust the structural rib reinforcement properly in vertical planes, with the temporary adjustable lateral rods provided for that purpose. This type of hinge reduces to a minimum the possibility of eccentric stresses in the ribs.

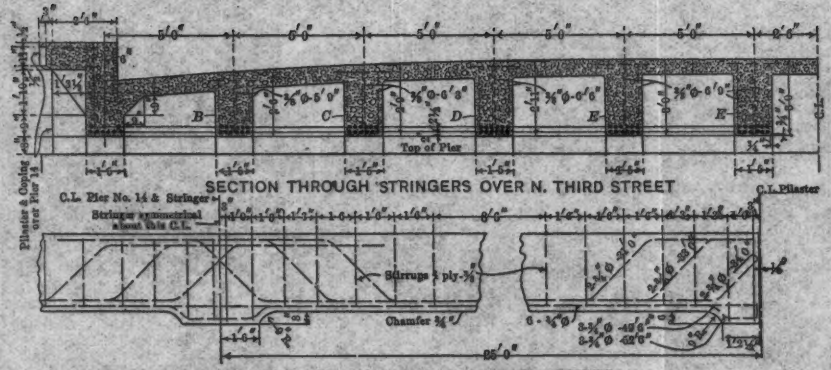
Bearings similar to these hinges had previously been used for some slow-moving multiple trucks, carrying extremely heavy loads. In this case, movement in all directions was necessary to take up the inequalities in the track. These bearings gave perfect satisfaction.

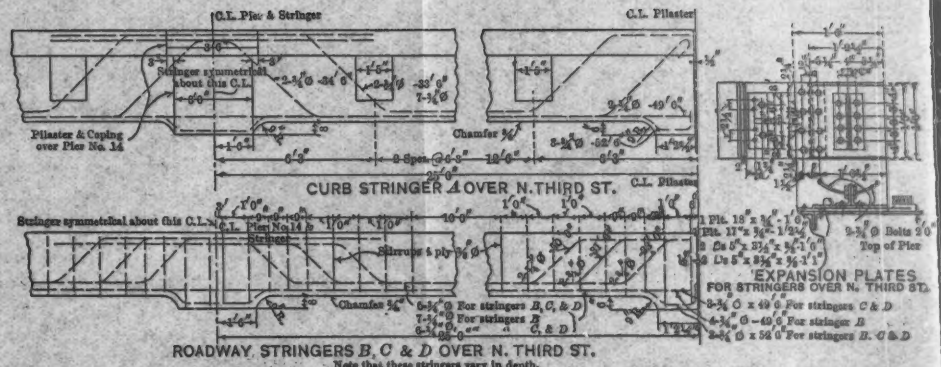
In proportioning the hinge castings, much the same method was followed as in the design of a column base. A section was taken through the diagonal rib of the hinge, at the junction of the rib with the body, or shaft, of the casting, and the tensile, compressive, and shearing stresses on the section were computed. A section was also taken through the center of the hinge, and the stresses on this section were computed, on the assumption that the reaction on the base of the casting produced moments at right angles to this section, instead of radially, as had previously been assumed. The resultant of the radial and direct compressive stresses at the circumference of the shaft of the casting, was also investigated.

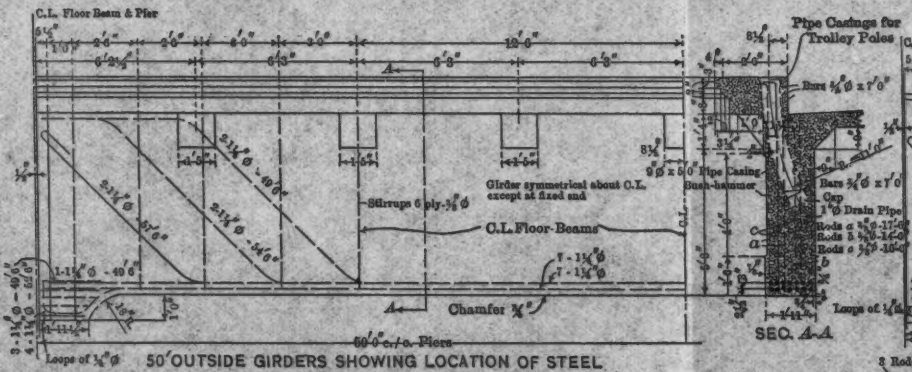
The camber of the arch spans was computed for full dead and live load, with impact, combined with temperature and an allowance for shrinkage. The rise of the structural ribs was increased by the amount of the camber. The total calculated camber for the longest span was about $3\frac{1}{2}$ in.

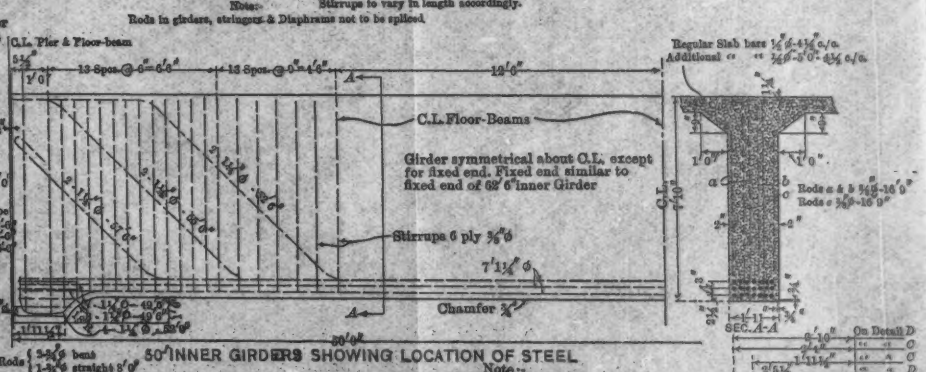
In the design of the main piers, considerable attention was given to the question of protection against scour. Pier No. 2 was given particular attention because of the fact that it is only a short distance below a power dam having a fall of about 15 ft. The bottom of the footing course was placed at about 5 ft. below the bed of the stream. Oak piles were provided, extending about 15 ft. below the bottom of the footing. The sheet-piling for the coffer-dam was driven about 8 ft. below the bottom of the footing, and was left in place. The banks of the stream at this point were also protected by a large quantity of rip-rap. These precautions, together with the fact that the material in the river bed at this point is a stiff clay not likely to erode, were believed to afford ample protection against scour.

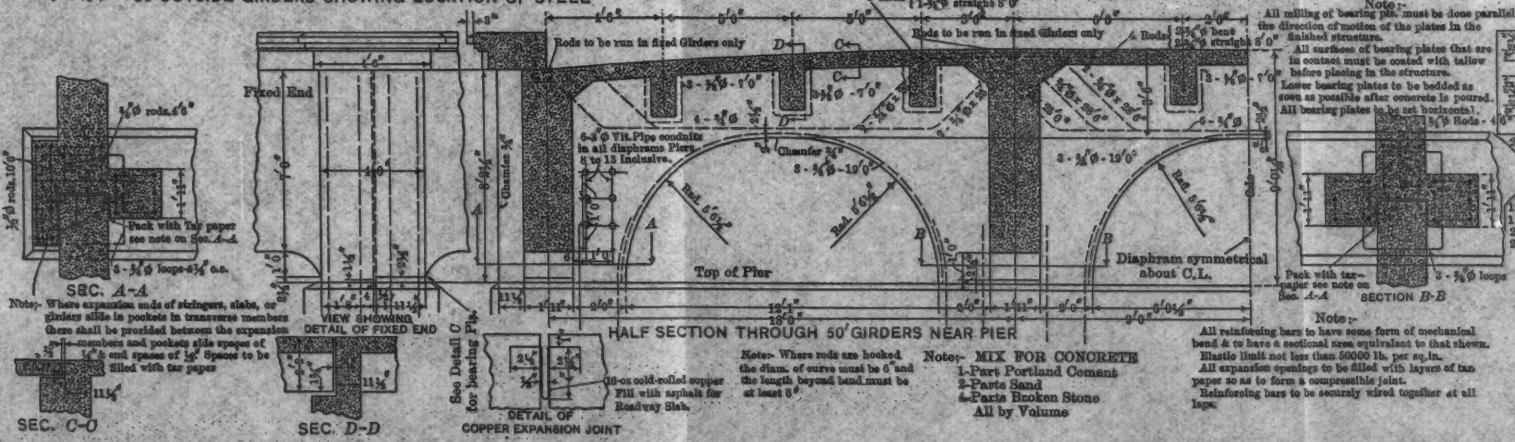
Several different designs and estimates were made for Pier No. 2 before a satisfactory solution was reached. The following were considered: First, a pier similar to Pier No. 1, founded on bed-rock; second, a pier having its base at about the level of the bed of the river, with the vertical loads carried on eight cylinder piers, two under each line of arch ribs; third, a pier resting on piles driven to rock;











Note:- Where expansion ends of stringers, slabs, or girders slide in pockets in transverse members there shall be provided between the expansion members and pockets side spaces of ½" and space of ½" Spaces to be filled with tar paper

Note:- Where rods are hooked the diam. of curve must be 6" and the length beyond bend must be at least 6".

Note:- MIX FOR CONCRETE
1-Part Portland Cement

and fourth, the pier as built, having moderately spread footings, but with a portion of the load carried on piles which do not extend to rock.

The first scheme was abandoned because of the cost, which would have made that of the structure exceed the appropriation. The second scheme was considered inadvisable because of the difficulty of taking care of the unbalanced horizontal thrust. As the vertical load would have been carried down the cylinders to rock, the friction between the pier base and the material under it could not safely be counted on to resist the horizontal thrust. There then remained, to resist this thrust, only the pressure of the earth against the body of the pier and against the cylinders. Computations indicated that this resisting pressure would be insufficient, unless the body of the pier was extended to a considerably greater depth. This would have made the cost too great. The third scheme was rejected for practically the same reasons as those given above for the second scheme, and also because, after investigation, it was considered doubtful whether piles could be driven to rock through the mixture of sand and gravel overlying it. The fourth scheme proved to be the cheapest of those considered, and was believed to be the most feasible. Therefore it was adopted, with the provisions mentioned above to protect the pier from scour.

The small piers were designed for full vertical load only, using the unit pressures mentioned previously.

Rankine's theory of earth pressure was used in the design of the retaining walls. The weight of the earth fill was taken at 100 lb. per cu. ft. A superposed load of 100 lb. per sq. ft. was assumed, to take care of the roadway and sidewalk loads. For convenience in computing the pressures, the unit weight of the fill was considered to be increased by the ratio, $\frac{d'}{d}$, where d is the actual depth of fill, and d' is the actual depth plus the depth of the imaginary fill required to produce the same unit vertical pressure as the superposed load. In the foregoing case, $d' = d + 1$ ft. For the higher sections, this increase is negligible, but, for the lower ones, it is worth taking into account.

In concluding this portion of this paper, a few words in regard to the advantages of the three-hinged, ribbed arch may be in order.

So much has been said on this subject, that little that is new can be brought out. However, to go over the ground again briefly, it is evident that the stresses in an arch of this type are statically determinate, and can be computed with as much accuracy as the loading assumptions and computations of the dead weight warrant. Temperature stresses and those due to settlement are eliminated, and the computations, though somewhat long, are simple. Practically, the only disadvantage is the cost of the hinges. In the Main Street Viaduct this item amounted to about 3½% of the total cost. This is more than it should have been, owing to the high price paid for the steel castings. Even at this price, when all the advantages of the three-hinged arch are considered, the money paid for hinges is well spent. The ribbed arch has two great advantages over the barrel, or solid arch. These are lightness, with consequent saving in cost, and the fact that water-proofing is not required. The latter, alone, is enough to recommend it to those who have had trouble with this feature of arch construction.

The increasing use of the three-hinged ribbed arch, both in the United States and in Europe, is evidence of its many advantages.

Construction.

Contractor's Plant and Equipment.—Work on the Main Street Viaduct started early in December, 1912, and was finished in March, 1914. The climate of Fort Worth is such that concreting can be carried on at all seasons of the year. The only interruptions were those due to rains, which were infrequent.

The general contractor's plant and equipment consisted of a central mixing plant, two distributing towers, with hoists, chutes, etc., an electric locomotive and cars for transporting concrete, derricks and clam-shell buckets for handling excavation and materials, a pair of driver leads suspended from the boom of a derrick, and the usual equipment of smaller tools and appliances. The sub-contractor for the structural steelwork had a steel stiff-leg derrick, a derrick car, two gin-poles, a two-bent timber gantry traveler, and the necessary hoisting engines and minor appliances. With the exception of one hoisting engine, all the general contractor's equipment was electrically driven, current being obtained from the local power com-

pany and transformed at the site. The sub-contractor's equipment was operated by steam.

While the pier excavations were under way, the mixing plant was being built near Pier No. 3 on the down-stream side of the structure. This consisted of an elevated hopper divided into two parts, one for rock and one for sand, a measuring box for sand and one for stone, and a mixer capable of handling a batch of a little more than 1 cu. yd. of concrete. Behind the mixing plant was a stiff-leg bull-wheel derrick for unloading materials and for supplying the hoppers of the mixing plant. Materials were brought to the site on cars, on a spur-track which crossed the line of the viaduct alongside of the mixing plant.

Concrete was discharged from the mixer into steel hopper cars drawn by an electric locomotive running on a narrow-gauge track. The concrete was carried in these cars to the two distributing towers, where it was hoisted and conveyed through the chutes to its destination. The larger of these towers was stationary, and was about 200 ft. high. This tower served the portion of the viaduct, between Pier No. 4 and the South Abutment, except where concrete was discharged directly into the footings of Pier No. 3 from the mixer. The other and smaller tower was built so that it could be moved when required. It served the portion of the structure between Pier No. 4 and the North Abutment. For the retaining walls, concrete was carried in the hopper cars to the north end of the walls, where it was switched back on a trestle midway between the walls, and having the track parallel to and about 6 ft. above the tops of the walls. From this trestle the concrete was passed through chutes into the walls.

Construction Methods.—Steel forms were used where there was sufficient duplication to make them economical. They were especially advantageous on the girders and floor system, which had been laid out with the view of making the work as simple, and giving as much repetition, as possible. For instance, all floor-beams were made alike, so far as the dimensions of the concrete were concerned; all panel lengths, and consequently all stringers of each kind, were alike. The wall forms were made up of squares and rectangles of such size that they could be handled readily by two or three men. These forms were stiffened by angles, and were bolted together by bolts passing through the flange angles. They were braced by timber verticals and

shores. The grades of the walls, coping, and any irregular portions were formed in wood. Sufficient deck and girder forms were provided to make two of the 62 ft. 6-in. girder spans. These forms were reinforced in order to prevent bulging and deflection between panel points.

The resulting surface finish was in general very good, and required little working, after the forms were removed, to produce the desired results. On removing the forms, the surface was bush-hammered, and all fins and lips left at the junction of the form sections were removed. In some cases where the forms had been insufficiently braced untrue surfaces were corrected by bush-hammering. Where necessary, the surface was rubbed down with carborundum blocks, and washed with neat cement grout, which was rubbed into the work. As a result of this treatment the surfaces present a neat and uniform appearance, which is very pleasing. Steel forms were used for the railings. The panels and hand-rails were cast on the ground, and erected; the posts and foot-rails were cast in place. Particular attention was given to the surface finish of the railings. All surfaces which would be exposed in the finished work, were rubbed down with carborundum blocks as soon as possible after the removal of the forms. The work was then treated with a thin coat of neat cement grout, well rubbed in, and the surplus grout washed off. This process was repeated until the surface pores were filled, and the work presented a smooth uniform surface.

After the main piers were finished to the tops of the skewbacks indicated on the plans, by the lines, *X-X*, the hinges were set in pockets provided for that purpose. The space between the base of the hinge casting and the back of the pocket, of about $\frac{3}{4}$ in., was filled with neat cement grout, and the pocket was filled with concrete to the line, *Y-Y*, shown on the plans, leaving only the socket of the hinge exposed. After the concrete had become thoroughly set, the erection of the structural steel reinforcement was commenced. This was done before finishing the piers above the lines, *X-X*, in order to facilitate the handling of the erection equipment.

Two methods were used in erecting this structural reinforcement. Spans *C*, *D*, and the south arm of Span *A*, were raised with derricks and gin-poles, and without the use of falsework. For Span *B*, a two-bent timber gantry traveler was used. This traveler also raised the north arm of Span *A*. Span *D*, which is the shortest and lightest

GENERAL NOTES

Structural reinforcement to consist of 3 steel ribs of section shown.
Stresses given are in 1000-lb. units, + denoting compression and—tension.
Allowable stress on rivets to be 12000 lb. per sq. in. for shear and 24000 lb per sq. in. for bearing.
Open-hearth structural steel to be used. Hinges to be of cast steel.
Material and workmanship to be in accordance with Manufacturer's Standard Specifications.
Rivets ⅞" wherever possible. Minimum thickness of gussets to be ⅝".
All web members to have at least 3-rivet connection and chord lacing to have 2-rivet conn.
All reinforcing rods to have some form of mechanical bond and to have a sectional area equivalent to that shown. Elastic limit not less than 50000 lb. per sq. in.
If rods are spliced they must be lapped at least 48" and securely wired together.
Ordinates given are to neutral axis of finished rib under full dead and live loads.
Forms for ribs and braces to be supported on structural steel ribs.
All Rivets to be spaced so that net section of L will contain but one rivet hole.

FIG. 11.

of the four, was raised by a stiff-leg derrick placed on top of the skewback course of Pier No. 3, and by a gin-pole. The derrick handled the south halves of the ribs, and the north halves were raised by the gin-pole. After this span was finished, the derrick was moved to the top of the skewback course of Pier No. 2, where it was used to raise the south half of Span *C*, and to erect the gantry traveler. Span *C* is considerably heavier than *D*, and, consequently, in raising the ribs, the derrick had to be assisted by a gin-pole. The north half of the span was raised at the same time as the south half, by the derrick and the other gin-pole. The half ribs of both these spans were necessarily handled in one piece.

Low and comparatively light falsework was used for Span *B* and the north half of Span *A*. This was built at about the level of the coping under the skewbacks of the piers, and served to carry the traveler and such bents as were required to support the sections of the ribs. Each half rib was raised in two sections, and field-riveted.

When the steel had been erected, the ribs were carefully lined up in vertical planes with the adjustable lateral rods provided for that purpose, and the field connections were riveted. The next step was to place the reinforcing bars and to wrap the ribs and braces with heavy wire. The forms were then built in place, and supported from the structural reinforcement, in the manner indicated on the plans.

Span *D* was concreted in the following manner: Radial bulkheads were provided in each rib at distances of 22 ft. from each haunch hinge, measured along the rib, and also at points in each rib, 10 ft. from the crown hinge. The transverse braces were also bulkheaded off, so that concrete would not flow into them from the ribs. Chutes were arranged in such a manner that concrete could be discharged in any one of the haunch or crown sections by changing a series of gates. These gates could be changed at a moment's notice. Concreting was started in the haunch sections of the down-stream rib. Four batches, of slightly more than 1 cu. yd. each, were deposited in each haunch section, and alternating batches between the two haunch sections. One batch was then deposited in each of the crown sections, to keep the rib from being distorted. The same order was followed with each of the other ribs, except that, as the inside ribs are thicker than the outside ones, more batches were used for them at each lift. When all the ribs had received the first batches of concrete, as noted,

the process was repeated until the haunch and crown sections had been filled. Lagging was carried up the back of the ribs as the concreting progressed, to hold the concrete, which was necessarily mixed quite wet, in order to work well around the reinforcement. After setting for about 4 days, the bulkheads in the ribs were removed, the surface of the concrete was roughened up, and the closure sections of the ribs were concreted in about the same manner as the haunch sections. The transverse braces were not concreted until the rib concrete had set for several days.

In order to keep track of the distortion of the ribs while concreting was in progress, sash weights were suspended from the steel brace reinforcement close to each rib, at four points along the rib. One weight was placed at the brace on each side of the crown hinge, and one at each quarter point of the span. These weights were suspended by small wires, and carried scales which were wired to the weights. A stake was driven in the ground alongside of each weight, and a nail in the stake acted as a pointer on the scale. The initial reading was taken at each point, and another set of readings was made after each round of concreting. At first a slight settlement of the crown points was observed, followed by a slight rise. The distortion was less than had been anticipated, amounting to a maximum of about $\frac{1}{4}$ in.

The concrete in the ribs and braces was allowed to set for several days before the work of building the forms for the posts and deck of the span was begun. This portion of the work was concreted in the manner indicated under the head of "Loading." The posts were concreted, beginning at the haunches and working toward the crown. Then the deck was concreted from the crown back toward the haunches, with the exception of the middle section, over the crown, which was placed last, in order to provide for the expansion joint at the crown. The piers, in the meantime, had been finished to their full height, in order to insure stability and provide for the connection of the deck to the piers.

The concreting of the other spans was handled in practically the same manner as that just described. When the concreting of a section was started, it was carried through continuously, by working day and night if necessary, so that the work was made as nearly monolithic as possible.

UNIV. OF ILL.

The plant and equipment on the other viaducts was similar to that used at Main Street, but, of course, on a smaller scale. All four jobs were under construction at the same time, and were finished on or before the last of March, 1914.

Difficulties Encountered.—There was some difficulty, at Main Street, in the early stages of the work, in sinking the foundations of the main piers. Pier No. 1 gave the most trouble. The unstable character of the soil on the south side of the stream was responsible for this. Extra heavy timber sheet-piling and a large number of heavy shores of timber and steel were used. In order to give the material on the hillside south of the pier the least possible chance to slide, the excavation was made in four sections. The first section excavated was the down-stream quarter of the pier. This excavation was about 20 ft. in length, measured up and down stream. After rock was reached, the surface was carefully cleaned off and several drill holes were put down to test the rock. The surface of the rock was found to be very rough, with a slight drop in elevation away from the stream. The drill holes showed that the layers of rock were very thick and had only minute seams between them. There had been some fear that the pressure of the bank behind the pier might cause the pier to slide on the rock, before sufficient weight could be added to prevent it. With this in mind, preparations were made to cut a dowel in the rock so as to bond the pier and the rock together. The fear of sliding was dispelled when the extremely rough character of the rock was seen, and the dowel scheme was abandoned. The pier section was concreted up to the top of the 13 ft. 6-in. footing course, and the next section, which was the third quarter from the down-stream end, was excavated and concreted to the same height as the first. The up-stream quarter was next finished, and lastly the second quarter from the down-stream end. Of course, all longitudinal reinforcing bars in the portion of the pier below the top of the footing course, had to be spliced, on account of the method of construction adopted. Care was taken to bond the sections of the footing course together by vertical re-entrant joints extending the full height of the 13 ft. 6-in. course. Above the top of this course the pier was built as a monolith in the usual manner. In concreting the footing sections it was not thought advisable to remove all the shores as the concrete was carried up. Consequently, some of the steel members from the

old bridge, which had been used for shoring, were built into the pier and left.

At Pier No. 2 the only difficulty experienced was in driving the oak piles. These were about 20 feet long, and were driven to refusal by using a drop-hammer. Driving through the compact mixture of sand and gravel at this point was difficult. A bearing test of the material in the bottom of the pit after the piles were driven gave very little settlement under a load of about 8 000 lb. per sq. ft., with a loaded area of about 4 sq. ft.

At West Seventh Street there was considerable trouble with the erection of the structural reinforcement of the arch span. The equipment was not as good as that used at Main Street, and the work progressed slowly. The engineers had expected that this steelwork would be handled by derricks on the piers in much the same manner as at Main Street. The sub-contractor felt that the size of the job did not warrant this equipment, and decided to crib up the steelwork on falsework in the bed of the stream. This was finally accomplished, and the falsework was removed, after the field splices in the ribs had been riveted. While the riveting of the transverse members was under way, the erector removed some of the lateral rods in order to get at the rivets with less trouble. This was done in spite of the protest of the engineers' representative. The stiffness of the lateral connections held the arch in place for a while, but finally a strong wind, aided to some extent by the movements of the men at work on the span, caused the ribs to revolve sideways on the hinges, and then drop into the stream a short distance below. Fortunately, no one was killed, and but slight damage was done to the steelwork. The work of re-erecting and repairing the steel was begun, the ribs being supported on timber falsework in the stream in much the same manner as before. When the work was only partly finished, the freshet previously mentioned, which occurred in September, 1913, came down and washed out the falsework, again dropping the steel into the river. The work was finally replaced in good shape, after much loss of time and money. This freshet also did some damage to the falsework for the traveler at Main Street. Had the arches been under construction on falsework in the usual manner, much more serious damage would undoubtedly have resulted.

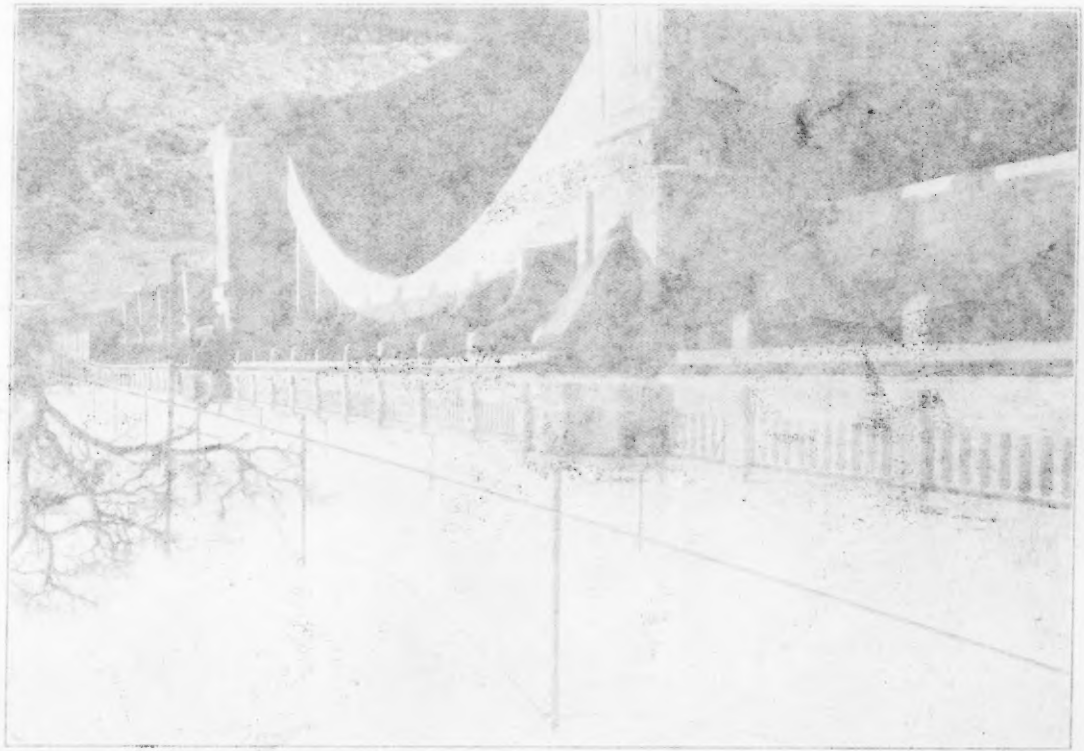

FIG. 22.—SAMUELS AVENUE VIADUCT.

FIG. 22.—SAMUELS AVENUE VIADUCT.

Figs. 12 to 22 show the work at various stages, and are self-explanatory.

Cost of Viaducts.—Tables 1 to 5 give the quantities for each of the viaducts, and the unit prices bid by the successful contractor. They also give the cost per linear foot of each structure, the cost per square foot of horizontal and of vertical projection, and the cost per cubic foot. The cost per square foot of vertical projection is based on the area of projection of each structure between the finished

TABLE 5.—Summary of Cost of Four Viaducts.

	Main Street.	West Seventh Street.	Samuels Avenue.	East Fourth Street.
Cost per linear foot of structure	$244.60	$123.45	$141.29	$130.59
Cost per square foot of horizontal projection	3.66	2.10	3.28	3.02
Cost per square foot of vertical projection	6.34	6.93	3.53	3.60
Cost per cubic foot of volume between finished ground line and crown of roadway	0.091	0.119	0.082	0.083
Total estimated cost, including paving, lighting, and engineers' fees	$428 882.00	$127 472.00	$63 584.00	$58 766.00

ground line and the top of the roadway. For the horizontal projection, the extreme width over the copings or stringer mouldings was taken. In computing the cost per cubic foot, the volume included between vertical planes through the copings, and between the finished ground line and the top of the roadway, was taken. The total, on which the above unit costs are based, is the cost of the structure based on the contractor's unit prices and the quantities as given in the tables, to which has been added the cost of the paving, lighting, and engineers' fees.

Personnel.—The work was designed and its execution supervised by Messrs. Brenneke and Fay, Consulting Engineers, of St. Louis, Mo. The writer, as Principal Assistant Engineer for that firm, was responsible for the design of the viaducts, and exercised executive supervision over the work. L. H. Faidley, Jun. Am. Soc. C. E., had charge of the detailed work of preparing the plans, and William Holden, Jun. Am. Soc. C. E., was in direct charge as Resident Engineer.

The contract for the Main Street Viaduct was awarded to the Hannan-Hickey Brothers Construction Company, of St. Louis. The Tarrant Construction Company, of Fort Worth, had the contract for the West Seventh Street Viaduct, and the other two structures were awarded to the McKensie-Williams Construction Company, of Webb City, Mo. The Virginia Bridge and Iron Company, of Roanoke, Va., were the sub-contractors for the structural steelwork of the Main and West Seventh Street structures, and erected the steelwork at Main Street. Austin Brothers, of Dallas, Tex., were the sub-contractors for the erection of the steelwork at West Seventh Street.

In conclusion, the writer wishes to express his thanks to Mr. Faidley, and to Mr. Holden for valuable assistance in the preparation of this paper.

AMERICAN SOCIETY OF CIVIL ENGINEERS

INSTITUTED 1852

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

ADDRESS AT THE ANNUAL CONVENTION, IN BALTIMORE, MD., JUNE 2D, 1914.

By Hunter McDonald, President, Am. Soc. C. E.

In accordance with the provisions of the Constitution, the President must deliver an Annual Address. It is not difficult to understand why such a provision was placed in the Constitution of earlier days. The publications of the Society were then the principal means for disseminating information on engineering subjects and exchanging views thereon. In the present day, however, each separate branch of the Engineering Profession is provided with its own special organ, published for profit, and they vie with each other in presenting accounts of engineering work in most attractive and readable form. Society journals have become mere repositories of facts and opinions, and are not often read voluntarily, but are usually carefully preserved and are invaluable as sources of reference by reason of their authentic character and prestige. We should carefully guard and preserve the high quality of our publications, and all papers intended to promote private interests commercially should be denied admission.

In the earlier days the President was charged with the duty of reviewing the engineering progress of the previous year. A literal compliance with such a provision now would be a stupendous task, and, even in the hands of a skilled and entertaining author, would be uninteresting to the members because they have seen it all in such very attractive form from week to week in engineering journals.

Fortunately for me, and doubly fortunate for my audience, the character of the presidential address is no longer prescribed, and any amount of latitude seems permissible; at least such seems to be a reasonable inference from a cursory examination of some of the addresses of my predecessors in office.

Taking advantage of such liberty, and having due regard for the patience of my audience, I shall briefly refer to some of the more important matters of interest which the present year brings to engineers, and shall then direct attention to some matters concerning the welfare of our Society and the profession of which it is the foremost exponent.

It is a matter of pride and cause for congratulation that the most stupendous work of civilization, the Panama Canal, is about to be presented to our Government by men of our profession, completed greatly in advance of the time when it was due, and absolutely free from any taint of scandal, graft, or incompetency in any of the stages of its progress.

Fresh from the glories of this achievement, our Government has entered upon two more gigantic tasks to be performed in untried fields. These are the valuation of the railroad and telegraph properties of the United States, and the building of railroads in Alaska. The first of these projects is engaging the thought and time of a large number of our profession, and has already resulted in greatly increasing the demand for and compensation of engineers at a time when, on account of general stagnation in industrial development, many would otherwise be idle. In this work engineers have the opportunity to show to the country that they, more than any politicians or lawyers, are qualified to ascertain and fix the underlying principles upon which this valuation should be made, and then to follow this up by the actual working out of the results. It is a matter of encouragement to our brethren—although probably not to those of our citizens at large, who have given the matter much thought—to reflect, that from five to ten years will be required to complete the task, and, when it is done, a large force of engineers must be constantly employed, both by the railways and the Government, to keep the work up to date. It is not for us to say whether or not "the game is worth the candle", but to address ourselves to the task set before us and demonstrate our fitness for the responsibility.

The science of such valuation is new. In 1897 it became my duty to serve as one of a committee to value a piece of railroad property for a joint terminal. Being inexperienced, I sought from the pages and editors of technical journals and from other engineers some information as to the basis for such valuation. I was unable at that time to secure it. Now there is so much in print on the subject that is with difficulty that the chaff can be separated from the grain. We have a Special Committee which is wrestling with this problem and its preliminary reports indicate that important results are to be expected from its labors.

A commission of engineers is now charged with the duty of selecting a route for the main line of a railroad from some harbor on the southern coast to the central part of Alaska, and to determine what and where branches are to be built. When the location is determined, it is probable that the building of the roads will be entrusted to the United States Corps of Engineers. It seems improbable that the roads will ever be operated by any agency other than the National Government. An opportunity presents itself here for civil engineers to demonstrate their fitness for responsibilities other than the mere application of mathematics. A civil engineer is now Governor of the Canal Zone, and another should be General Manager of the Alaskan Railroad when the time for its operation arrives. It is not necessary to state that his staff should be composed of engineers. An engineer has recently been chosen as manager of one of our large cities. Many are being placed on City Commissions.

Persons who are charged with the responsibility for the wise expenditure of public money are more and more inclined to turn to the engineer for advice as to how to do it, and to recognize the fact that civil engineers are fit for something else than preparing blue prints, setting stakes, and running instruments. We are now on the threshold of new responsibilities, and we must set ourselves faithfully to the task of preparing to meet them. Good engineering consists largely in meeting emergencies with the resources at one's disposal. The man who does it is always in demand.

Much of the space in the addresses of some of our Past-Presidents has been devoted to discussing the status of the engineer, the ethics of the profession, and how to compel an apparently unwilling public to recognize the fact that engineering is a profession. Complaint is

rife that we do not get our just deserts, and that something not clearly defined must be done to remedy this injustice.

I have been tempted to delve somewhat deeper into the origin and present meaning of the word "engineer" than my predecessors in office have done. Realizing my own lack of fitness for the task, as far as the origin is concerned, I called in a specialist on etymology, Dr. Bert E. Young, Professor of Romance Languages of Vanderbilt University, and lately honored by the French Government with the decoration of Officer of Public Instruction for distinguished services in the promotion of French literature.

I quote his statement in full:

"I take pleasure in furnishing the best information I have as to the origin of the word 'engineer':

"*Engineer,* formerly *enginer,* or sometimes *ingener,* Middle English *engyneour,* from the Old French *engignier* or *engigneour,* or shorter *engineur.* This from Middle Latin *ingeniarius,* one who makes or uses an engine, especially a war engine. *Engine* is from Latin *ingenium,* an invention, an engine.

"The French word *ingenieur,* a semi-learned form, seems to come down by a slightly different road, being from the hypothetical Middle Latin word *ingeniator* from *ingeniare* from *ingenium,* an engine. Or else the Modern French *ingenieur* is an alteration of the better form *engigneur,* mentioned in first paragraph.

"*Genie* from Lat. genius, orig. a spirit, extended as a term of war to the sense of *art* of attacking or defending fortified places, etc., and then to the arm of the service devoted to military or naval engineering.

"*Ingenuity* from French *ingenuite* from Lat. *ingenuita (t)s* from *ingenuus,* native, born of free parents, frank, generous. *Ingenious* from Lat. *ingeniosus,* gifted with genius or natural capacity. Lat. *ingenium* from Old Latin *genere.*

"Apparently all go back to the ubiquitous root, $\sqrt{\text{gen}}$, to bear, to produce, to give birth to.

"Misc. remarks:

"Considering the derivation of ingenuity, there must have been confusion of Lat. *ingenuus* and Lat. *ingeniosus.* These should be almost opposite in meaning. I suppose an *engineer* ought to be both *ingenious* and *ingenuous,* artful and artless, sophisticated and unsophisticated, bond and free. According to the above, I should say that the man who pronounces *injine* is only atavistic.

"Ex.—'In hys court was a false traytoure, that was a grete Yngynore (plotter). (Halliwell, 1420).'

"Ex.—'The most prime Engineers of Oaths that ever the world knew. (Butler, 1680)'.

"Ex.—'For 'tis the sport to have the enginer hoist with his own petar. (Shak., 1602, Ham. iii, 4, 206).'

"Ex.—'The Ingener of this practice—was a Portugal. (Carew, 1620).'"

From the Oxford Dictionary, which no doubt gives the prevailing English view, I have extracted the following definitions and examples of the use of the word "Engineer".

"One who contrives, designs or invents. Ex. 1611, Rich, Honest age, 1844 (36) 'Yet you cannot deny them to be the devil's engineers'.

"1635, R. Gibbs in Spurgeon 'That great engineer Satan'.

"A constructor of military engines (Obsolete). One who designs and constructs military works for attack or defense. 1325 Coer De Leon 1387—'a tour ful strong, that queyntyly engynours made'.

"A soldier belonging to the division of the army called engineers, composed of men trained in engineering work. Ex., Porter's History, Royal Engineers. 'This day (May 26th, 1716) may thereafter be taken as the one on which the engineer branch blossomed into a distinct corps.'

"One whose profession is the designing and constructing of works of public utility, such as bridges, roads, canals, railways, harbors, drainage works, gas and water works. From the 18th Century, also civil engineers (from the military).

"Ex. 1792 Smeaton Reports (1797) I pref. 7. 'The first meeting of this new constitution, the Society of Civil Engineers, was held on the 15th of April 1793.' Ex. Eddyston L. introduction—'My profession of a civil engineer.'

"A contriver or maker of engines (specifically mechanical engineer).

"One who has charge of a steam engine. In England only with reference to marine engines. In the United States often applied to the driver of a locomotive. Ex. 1860, Bartlett's Dictionary. American, Engineering, 'the engine driver on our railroads is thus grandiloquently designated'.

"Engineman, one who works or helps to work a fire engine. One who attends to a stationary engine. The driver of a locomotive."

From other English authorities:

March's Thesaurus Dictionary. "One versed in any branch of engineering. To manage skillfully. The science and art of building, making and using engines and machines."

Hallowell's archaic and provincial words. "Engin, wit, contrivance (Lat.). Inginous, inventive (Jonson)."

From Joseph Wright's English Dialect Dictionary. "In 1649 Gray wrote 'Master Beaumont a gentleman of great ingenuity and rare parts adventured into our mines, who brought with him many rare engins. The memory of these 'rare engins' survives in the name of the seam

which he appears to have discovered, still called the engin seam." It will be noted that Beaumont was practicing civil engineering at quite an early date.

From the Century Dictionary, presenting the American view, the following:

"A person skilled in the principles and practice of any department of engineering. Engineers are classified according to the particular business pursued by them, as *military, naval* or *marine, civil, mining, mechanical* and *electrical* engineers.

"To work upon; ply; try some scheme or plan upon.

"Ex.—'Unless we *engineered* him with question after question, we could get nothing out of him.'—*Cowper.*

"To guide or manage by ingenuity or tact; conduct through or over obstacles by contrivance or effort; as to *engineer* a bill through Congress."

Through the kindness of our Secretary, Mr. Hunt, I have been able to secure the following translations from the Dictionnaire de la Langue Française:

"One who plans, lays out and directs field work and fortifications, for attacking, defending or fortifying places.

"Ex.—'Then he (Peter the Great) has had even a school of engineers in a country where no one (before him) knew the elements of geometry, Volt. *Charles XII,* I.'

"One who directs [private] works or public works, such as the construction and maintenance of roads and bridges, working of mines, etc. Engineer of bridges and roads. Mining Engineer, Naval Engineer or Marine Engineer, Railroad Engineer.

"Civil Engineer, name given to engineers who are not trained in technical schools or who work for private industry.

"Naval Architect or Engineer, one who applies himself to the art of naval construction.

"Topographical Engineer, one who draws maps. Hydrographical Engineer, See Hydrography.

"Engineer for mathematical instruments, one who makes mathematical instruments."

Also, from Cotgrave's Dictionary of the French and English tongue:

"Enginier —An engineer; a maker of engins.
Enginer —Engigner.
Engigner —A deceiver, beguiler, cousener; also an enchanter.
Engin —An engin, toole, instrument; also understanding, policie, reach of wit; also suttletie, fraud, craft, wiliness, deceit.
Ingenieur—An enginer, engine-maker; fortifier."

Mr. Hunt also furnished me the following translation from Grimm's Deutsches Wörterbuch:

"Engineer, n.—This word of the present day, for military architect, surveyor, introduced from a foreign language in the 17th century represented an artful calculating person in general. Ex.—'He who wishes to bring Germans into an understanding must be a very good and wise engineer (schemer, calculator)'. Weidner's, Zinkgres, 3, 158."

No trace of the use of the word "Engineer" or of any of the words from which it is derived in describing the building of any of the ancient structures has been found. That engineers of great skill existed is evidenced by monumental and written records, but they were designated otherwise, as for example: Frontinus, in his water supply of the City of Rome, as translated by Clemens Herschel, M. Am. Soc. C. E., mentions *moduli* (levelers), *scientia* (builders), *agrimensores* and *geometricii* (land surveyors), *architectos* (architects), and *Curator Aquarum* (Commissioner of Water Works), but none of the Latin words from which the word "engineer" is derived, are used in connection with the process of building or maintaining. The conclusion is inevitable that the name at least is comparatively modern, and that the attempt to class the calling among the learned professions is still more so.

John Smeaton was the first engineer to style himself Civil Engineer (probably in 1782).*

In the Annual Address of Mr. Charles Hawksley, President of the Institution of Civil Engineers, 1901, an extensive quotation is made from the Report of the Council, for the Session, 1885-86. A portion only is repeated here:

"'The honor of having originated the Institution is often assigned to Smeaton, or to Telford, but the idea is erroneous in both cases. Smeaton died many years before it was thought of, and Telford only joined it after its establishment.'

"A Society of Engineers, still existing, was founded by Smeaton in 1771; it includes many of the most eminent members of the profession, but it is rather of the nature of a social club than of a scientific association, and has no connection with this Institution."

To those who are interested in the beginnings of engineering, I would recommend an examination of the two papers above referred

*See discussion by Clemens Herschel, M. Am. Soc. C. E., of Paper No. 472, entitled "Beginnings of Engineering", by the late J. E. Watkins, Assoc. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. XXIV, p. 382.

to and the following: Annual addresses of Past-Presidents William E. Worthen, 1887 (*Transactions,* Vol. XVII), and William P. Shinn, 1890 (*Transactions,* Vol. XXII), also of Charles B. Vignoles, F. R. S., Past-President, Institution of Civil Engineers, 1870 (*Minutes of Proceedings,* Vol. XXIX).

On page 604 of *Engineering News,* May 26th, 1910, is an entertaining paper entitled the "Origin and History of the Profession of Civil Engineering". A foot-note describing it reads as follows:

"An appendix to the Presidential address of Jas. C. Inglis, President of the Institution of Civil Engineers of Great Britain. Abridged from the account contained in the life of Sir William Fairbairn by the late Dr. William Pole, F. R. S., Hon. Secretary of the Institution."

A portion of the beginning is quoted:

"The root of both the words, Engineer and Engine, is found in the Sanscrit *jan,* to be born, from which came the Greek form γεν, and the Latin *gen,* the latter being embodied in the old verb *genere,* with its compound *ingenere* (changed into *ingignere*), to implant by birth, and in their later substantive *ingenium,* an innate or natural quality.

"The old Latin verbs, *genere* and *ingenere,* gave rise to the French form, also a verb, *s'ingenier.* This is of great antiquity, and from its comprehensive and useful meaning it has continued in use down to the present time, being found continually in modern French writings. The import of it has nothing whatever to do with engines or machines, but is purely psychological. It is given in Littre's great French dictionary:

"'*Chercher dans son genie, dans son esprit, quelque moyen pour reussir.*'

"Now, all authorities, including our own great Lexicographer, agree that this word is the true origin of the word 'Engineer', and thus we arrive at the interesting and certainly little-known fact that an Engineer is, according to the strict derivation of the term, not necessarily a person who has to do with engines, but any one who seeks in his mind; who sets his mental power in action, in order to discover or devise some means of succeeding in a difficult task he may have to perform."

There are sufficient divergences of authority and definitions in the above quotations to give room for any amount of argument. I will be content with simply recording them.

These matters are mentioned primarily as leading up to a consideration of the condition in which the profession in this country

now finds itself. There is ample evidence that the word "Engineer" is now applied alike to the designers of engineering works and to the operators of engines. It is also evident that civil engineering is now considered by many to be a branch of engineering. In the language of the late Grover Cleveland "It is a condition and not a theory which confronts us." We could not, if we desired, compel the public to call locomotive engineers "enginemen" or "engine drivers", nor stationary engineers, "power superintendents", notwithstanding the fact that such they are. President Worthen in the address above referred to says:

"I would drop the term civil as embracing too large a profession, and adopt prefixes, as military, hydraulic, railway, mechanical, steam, electric and other divisions, when these are adopted as specialties."

His idea seems to have been merely to divide civil engineers into different classes. He does not mention civil engineers as one of the classes.

Until recently, I have also been inclined to the view that we should drop the word "Civil" from the name of our Society, but a closer study of the matter confirms me in the opinion that we should retain it. I think there can be no question but that civil engineering embraces all engineering except that connected with the actual conduct of war. The fact that the military engineer "in piping times of peace" performs the work of the civil engineer constitutes no distinction.

Conscious of our pre-eminence, this Society has been content to sit still and let the branches of our profession grow up independently until they have become of such importance as to force us to accept the meaning of the word "Civil Engineer" as indicating a specialty or division of the profession. This is a false position, and we alone are responsible for it. Smeaton evidently intended to make it a specialty, but he could not have known, at the time he referred to it, how intricate the divisions of the specialty were to become. Had we pursued a course similar to that of the engineers of Germany we would not to-day find ourselves in the humiliating position of being asked to substitute the word "Professional" for the word "Civil" in the bill recently pending before the New York Legislature for the regulation of the practice of civil engineering, before the other societies would co-operate with us in securing a bill which would be acceptable to the entire profession.

Believing that it would be interesting to know the number of the various kinds of engineers which go to make up our membership, I requested the Secretary to prepare from the List of Members a classification. After much labor it has been accomplished and is presented herewith in tabular form. It will be noted that in this classification our Secretary treats civil engineers as one of the divisions or classes. Under the conditions, he could not do otherwise.

I have alluded to the status of the profession in Germany, and will now describe its condition more at length, also referring briefly to conditions that exist in a few other countries. This is done with a view of comparing conditions in these countries with those in our own.

My information regarding Germany is taken from an article in *Engineering,* London, December 20th, 1912, entitled "The Verein Deutscher Ingenieure". It was founded in 1856. Quoting verbatim, the dominating ideas are expressed under three heads:

"1. The society must in its activities embrace the whole of Germany. [This is remarkable in that it anticipated Bismarck's federation by 15 years.]

"2. Local sections (*Bezirksverein*) must be founded in all parts of Germany.

"3. A good journal must be published."

In 1865 it had 1 000 members; in 1875, 3 000; in 1885, 5 300; in 1895, more than 10 000; and in 1912, about 24 000.

It has for its object, as indicated by the printed statutes, the intimate co-operation of the intellectual forces of German technical science for the benefit of the entire industries of the Fatherland. This object is to be attained by meetings of the entire Verein and its local sections, the *Journal,* the establishment of libraries and reading rooms, the editing of important technical works, the instituting of engineering research on subjects of industrial importance. The membership embraces (*a*) engineers, and (*b*) those capable of advancing the objects of the Union. Contributions are made from the general fund toward the support of local sections. All members living within the Empire must belong to local sections. In one year 300 business meetings were held and 400 lectures on technical subjects were delivered. The question box is in use at all sections, and a general technical committee answers all questions not answered by the members of the section at the regular meeting. These local sections, as a rule, are in touch

with the educational and industrial powers of the neighborhood. Courses of instruction and excursions through works are arranged for, and visits are frequently exchanged between sections. "Sentiment plays a much more prominent part in the life of the local sections than English [and, I may say, American] prejudice would allow." Honors are bestowed on leading members as they reach advanced age. and "the social graces are not neglected." Headquarters, libraries, and reading rooms are often in hotels, to the mutual benefit of the section and the proprietor. Weekly meetings are held with tables reserved. Ladies attend the monthly meetings. Play on the skittle alley, and free and easy beer evenings are monthly features of some sections. The Board of Management of seven is selected by delegates from the sections, and this council controls, except on extraordinary occasions when they meet with the delegates. Local sections are self-governing, provided their constitutions are approved by the council and their actions further the society's objects. General annual meetings are held. The backbone of the organization is the *Journal*. In 1911 it had 2 200 pages of text, exclusive of the advertisements. News and proceedings of local sections are published. Books are reviewed with conscientiousness. Brief abstracts are given of important articles in more than 60 leading journals. They follow closely on the article itself, and are then reprinted on one side of the sheet, with room for marginal notes. Much space is devoted to correspondence. Original researches are encouraged, and grants are made from the general fund therefor. Medals are awarded for specially good work, and bad work is not permitted. In the supplement to the *Journal*, questions of financial, political, economical, and literary news are treated. The general aim of the supplement is to afford the engineer knowledge of the wider world which he serves, and to bring the needs of the engineering world before the sociologists, economists, and politicians. "The enormous number of members and the influential positions which many of them hold, make the Verein a power in the land, with a voice for the industrial elements such as no other country possesses." It has had great influence on technical education, and has banished Latin and Greek from the curriculum.

A new movement to inject engineering ideas into municipal and State administrations has been inaugurated and is meeting with great success. The framing of patent laws and the purification of

Character of Employment of the Membership of The American Society of Civil Engineers.

In the List of Members, February 10th, 1914, a large percentage of the total membership (19.72) do not give any specific occupation, and therefore cannot be classed. The numbers and percentages in the following Table, therefore, are based on the 5 864 whose occupation is given in such a way as to enable them to be classed at least with some degree of probable accuracy.

		Character of Employment.						Private Practice.

technical language has received attention. It has fixed mechanical standards as well as fees for engineers and architects. Needy members are assisted with charity. No correspondence tuition is allowed to be advertised in the journal. Branches in foreign countries are contemplated.

I have dwelt at considerable length on the abstract of this article because it shows what might have been accomplished in this country had the management of our Society shown the same interest in the profession at large as it has in the welfare of its members only.

In France the good of the entire profession has always been the object of the Société des Ingenieurs Civils, which is the title of the organization of the free engineers as distinguished from that of the engineers of the Ponts et Chaussées and other Government engineers. This Society was founded in 1848. It flourished from the beginning, and received many donations. In 1877 its new building was completed, and the Society moved into it. Government engineers are not eligible, but it was organized largely by Alumni of the Government schools. Its avowed objects are:

1. To throw light by discussion on obscure questions in civil engineering;
2. To assist in aiding the development of applied science auxiliary to civil engineering and to assist industries;
3. To extend professional teaching among workmen and shop foremen;
4. To investigate questions of industrial economy of administration, to increase the power production and wealth of the country;
5. To insure close relations among its members;
6. To act as a kind of employment bureau for its members; and
7. To establish a fund in case of necessity.

An examination of the year-book of the Society indicates a very prosperous condition, both as to finances and membership. The members are scattered over many colonies and foreign countries. Sections exist in all provinces.

The following is quoted from the List of Members of the Institution of Civil Engineers of Great Britain:

"The Institution of Civil Engineers was first established, and has since been incorporated by Royal Charter, for the General Advance-

ment of Mechanical Science, and more particularly for promoting the acquisition of that species of knowledge which constitutes the profession of a Civil Engineer; being the art of directing the great sources of power in Nature for the use and convenience of man, as the means of production and of traffic in States both for external and internal trade, as applied in the construction of roads, bridges, aqueducts, canals, river navigation and docks, for internal intercourse and exchange; and in the construction of ports, harbours, moles, breakwaters and lighthouses, and in the art of navigation by artificial power for the purposes of commerce; and in the construction and adoption of machinery; and in the drainage of cities and towns."

This organization is very similar to our own, and its status is so well known as not to require detailed reference here. All members admitted below the grade of Member are required to pass examinations. The list contains the names of more than 9 000 members of all grades.

The Canadian Society of Civil Engineers was organized in 1887. Its objects are:

1. To facilitate the acquirement and exchange of professional knowledge among its members; and
2. To encourage original investigation.

Article 2 of the By-Laws reads as follows:

"The term 'Civil Engineer', as used in this Society, shall mean all who are, or have been, engaged in the designing or constructing of railways, canals, harbours, lighthouses, bridges, roads, river improvements or other hydraulic works, sanitary, electrical, mining, mechanical, or military works, or in the study and practice of navigation by water or air, or in the directing of the great sources of power in nature for the use and convenience of man."

It will be noted that this Society conceives civil engineering as embracing all engineering activity.

The standard of membership is not as high as in the Institution or our Society, but candidates who are not graduates of recognized technical colleges are required to pass examinations. It is divided into four sections: Electrical, Mechanical, Mining, and General. Note the absence of Civil. Provision is made for branches in important centers. They have a published code of ethics, and in two Provinces, Manitoba and Quebec, the practice of engineering is limited by law to members of the Society. Efforts are in progress to secure similar

laws in all other Provinces. The list shows 2 627 members of all grades.

Members need no description of our own organization. While our growth has been phenomenal, and the standard of our membership is generally maintained at a high level, there is a wide-spread feeling that there is something wrong, and that we are not accomplishing the good there is in us. Section 3 of Article I of our Constitution reads as follows:

"Its object shall be the advancement of engineering knowledge and practice and the maintenance of a high professional standard among its members."

Our total membership in all grades is more than 7 400. I believe there are fully 40 000 men in the United States who are eligible for various grades of membership, in about the same proportion as the list is now made up. It is hardly safe to assume that the reason they are not members is because they cannot afford to be. I think it is safe to assume that though they value the prestige of membership, they feel that the benefits are too remote. The engineer's calling generally imposes isolation, and yet they all dearly love companionship and exchange of ideas with one another. What we need and ought to have is the establishment of State organizations and of sections in all important cities. This matter has been studied by a special committee and discussed at one of our Annual Meetings, but, because we felt that our duty ended with the welfare of our own members, as provided in the Constitution, the project met with no encouragement. It is true that we permit local members in large cities to band together and call themselves Associations of Members of the Am. Soc. C. E., but they, as organizations, have no voice in our government, cannot mingle with other local organizations, and, except in very large cities where no other sections already exist, the formation of prosperous associations is impossible. The history of such local associations is by no means flattering to our pride or good management. The result of our narrow policy has been that organizations, embracing members of all the callings allied to civil engineering, have sprung up in nearly all cities of 100 000 inhabitants, and other national engineering societies have their own local sections established in many of these centers, and are co-operating with other local organizations. Some of these societies are by no means local in scope. In the inde-

pendent local organizations the membership in many instances has not been of so high a standard as our own because of the necessity for a large membership in order to meet expenses, and, like the German and Canadian Societies, all classes are taken in. Nearly all these organizations contain some of our members who have joined, sometimes as a matter of civic pride and more often because they found at home that companionship which could not reach them through the medium of our *Transactions* from New York. All but a few of these local organizations are struggling for existence, and are unable to publish their papers and discussions. Some are prosperous, and one in Boston antedates our own organization by several years. It is the duty of this Society to extend a helping hand to all who need it, and to take the initiative in an effort to amalgamate gradually all engineering organizations into one homogeneous and co-operative mass, permitting each, as far as possible, to retain its name and identity. Some sacrifice on the part of all would no doubt be necessary. Union has not been possible among religious sects, but as I have heretofore shown, engineers are of necessity managers, and, with their spirit of fair play and good sense, ought to be able to get together. Call it what you will, the American Engineer Confederation, or better still, the American Confederation of Civil Engineers.

I would not lower our standard of requirement for membership, but, by extending local societies limited financial assistance where needed, we can raise the general standard, and, by doing this, can elevate the profession at large so as to make a printed code of ethics unnecessary.

The time has come for the engineer to possess his own. The public is awake to the advantages of sound engineering advice. We have it in our power, without taking sides in political contests, to exert a beneficial influence in National, State and Municipal affairs. Some of the matters in the conduct of which we should exert a marked influence are the following:

We should seek to stop the economic waste, caused by the improvement of unworthy projects for internal waterways and harbors, the means for which are often wrung from Congress on padded and duplicated commercial statistics, the principal object being to aid Congressmen in re-election.

We should seek to have the civilian engineers in the employ of the Government given proper recognition of their services in the matter of credit, rank, salary, and retired pay.

We should see that the mad schemes for flood control of our rivers are punctured before money is expended on them, and that practicable schemes, considering the entire drainage basin as a whole, are adopted and their execution begun on a sound basis as soon as possible.

In every State and in every city we should lend our organized influence toward the securing of safe and sane building laws, free from the bias of selfish private interests and trades unions; that public moneys derived from bonds and taxes are not squandered on impossible and unnecessary projects which have not been the subject of proper engineering scrutiny; that sanitary officers are chosen for their fitness, and not because they write M. D. after their names; and that sanitary methods of water supply and sewage disposal are adopted in the rural districts. We should make use of the non-technical press in all legitimate ways, in order to bring before the minds of the public at large the importance of the engineer in civil life. Whenever we let the people know that we are organized, not only for our own improvement and protection, but for the public good, we need have no fear of not receiving proper consideration. We are wont to twit our medical friends on the fact that they often bury their mistakes, while our's stand to plague us, but we dare not compare records with them on charities and public spirit.

Before undertaking to show others what they ought to do, we should first put our own house in order. Good engineering is good management. From our financial statement it would appear that we are in a very prosperous condition, which is no doubt true, and I wish to congratulate our past management on its wisdom and foresight in this respect, but are we getting all that we can out of our present resources?

Our Society house is located in what is fast becoming the business district of New York City. The present value of the land and building is not less than $600 000. Two large rooms are maintained as Auditorium and Assembly Room, respectively. One of these is used for the fortnightly meetings at which the attendance averages about 175. It will seat 500 persons. On the occasion of our Annual Meeting both are needed for the Smoker, but as most of the members prefer

the lower room, the 700 occupants find it uncomfortably crowded and badly ventilated. The annual ball was held this year at the Hotel Astor because the Society halls were inadequate.

There are 31 persons now employed in the building. It contains a library of 80 000 volumes, with room for 150 000, also a Reading Room which was used last year by 4 887 readers. Research work for resident and non-resident members is performed at cost by the Society's staff. Our stock of publications, costing about $25 000, is kept in the building.

Interest on the value of our property at 5% makes the rental we pay for this house about $30 000 per annum. It would seem possible and wise to issue bonds and erect a building, portions of which could be rented for a sufficient amount to pay our interest, establish a sinking fund, and give us rent free. The upper floors should be rented, preferably to engineer tenants, the street floors to merchants. The top part of the building would supply our offices, auditoriums, and perhaps a roof garden. The architectural possibilities should atone for any fancied loss of dignity. Using elevators nowadays is not considered a hardship. The amount now devoted to rent would go very far in aiding struggling local sections.

Pending the working out of these larger problems, there are minor steps which can be taken at once, which will add to the value of our membership.

The volume now called "Constitution and List of Members" should be published in the form of a year-book, containing all that it now contains, and, in addition thereto, a codification of the by-laws, which have been passed from time to time by the Board of Direction and are subject to change by it. There are other matters of general interest which might be profitably included.

The minutes of our Society are now published in the *Proceedings*. Few of the members preserve the *Proceedings* because most of the papers therein are duplicated in the *Transactions*. More important items of the *Proceedings*, including the Minutes of the Board of Direction and Annual Meetings and Conventions, should be included in the year-book, and would thereby be preserved without compelling the expense of binding and preserving volumes of *Proceedings*.

The classification which the Secretary has inaugurated should be a regular annual feature, and each member should be required to

return his calling at the same time as he does his address. Steps should be taken to provide automatically for transfer to the Associate class of all members who abandon engineering practice and devote themselves exclusively to the promotion or sale of patented articles and appliances.

The provisions for expelling members guilty of improper conduct should be made less complicated and the power be placed in the hands of the Board of Direction. The Board of Direction should be empowered, and required, to espouse the cause of any member who is the object of unjust attack. Fees should be paid to members for creditable extracts of engineering articles appearing in technical papers, and for unbiased book reviews, and the advisability of continuing the monthly notes of important engineering articles, now published in the *Proceedings,* should be investigated. There are many things in the "Constitution" that should be placed in the by-laws.

I am not prepared to suggest methods by which the ideals which I have heretofore rather vaguely outlined may be brought into realization, but I feel that whenever a thing ought to be done, a way can be found to do it, and I believe a representative committee of our Society should be appointed to study what we ought to do and how to accomplish it.

Before closing I would remind you that our next Annual Convention will probably be held on the Pacific Coast, and that, in connection with the Panama-Pacific Exposition, this Society is co-operating with four National Engineering organizations in the holding of an International Engineering Congress at this Exposition. The organization and conduct of this Congress is in the hands of a Committee on Participation, composed of the Presidents and Secretaries of each of these Societies and a local Committee.

It is expected that many foreign engineers will visit the Exposition and attend the Congress. They will come as individuals, in groups, and in organizations. A Special Committee on entertainment of these foreigners has been appointed by the five National Societies, consisting of two members from each. A meeting of these Committees has been held, and substantial progress made toward the union of all our engineering strength in the laudable purpose of properly entertaining these guests. We are going to show them that American Engineers can get together, notwithstanding their separate organiza-

tions. We are going to try, through this Committee, to organize similar committees from representatives of the five engineering societies and from local societies in all the cities at which any number of foreigners are likely to stop. These committees are going to try and secure co-operation of the civic organizations in all these cities so that our guests may feel that they are the guests of the country and not mere unattached tourists and sightseers. It seems to me that in securing the co-operation of these societies for the first time in their history, the first great step toward a unification of the civil engineers of America has been taken.

It has not been customary on occasions of this kind to refer to sad subjects, but I feel that I will be pardoned if I turn from practical things for a moment to call attention to the loss which our Society and your Board of Direction have sustained in the deaths of Mr. Emil Gerber and Past-President Alfred Noble. Mr. Gerber was a conscientious and practical member of the Board of Direction, and cheerfully gave his time to the profession. He was a member of two Special Committees, Steel Columns and Struts, and Stresses in Railroad Track. He was also a member of the Finance Committee. We shall miss him greatly. Mr. Noble was a member of the Special Committee on Valuation of Public Utilities and was Chairman of the Committee to Investigate Conditions of Employment of, and Compensation of, Civil Engineers. He was an Honorary Member of the Institution of Civil Engineers of Great Britain. For his great service in connection with the Isthmian Canal projects, this Nation owes him a debt of gratitude which can never be repaid. It should be our duty and pleasure to see that all our influence is directed toward securing, on the part of the Government, a fitting and enduring tribute to his memory.

I cannot close this address without giving expression to my deep appreciation of and thanks for the honor which was conferred upon me in selecting me for your President.

AMERICAN SOCIETY OF CIVIL ENGINEERS
INSTITUTED 1852

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

THE CLARIFICATION OF SEWAGE BY FINE SCREENS.

By Kenneth Allen, M. Am. Soc. C. E.

To be Presented October 21st, 1914.

Synopsis.

The object in presenting this paper is to bring before members of the Society who are interested in sewage disposal several devices for fine screening that have been installed within the last few years, with such data regarding their merits and defects as the writer has been able to gather from various inspections and by correspondence.

A secondary object has been to indicate the relative position of fine screening as a method of sewage treatment with respect to tank treatment, in the belief that, although the field for fine screening is distinctly limited, its possibilities are not yet fully realized.

No attempt has been made to give other than general or essential details regarding the types of screens discussed.

By fine screens is meant those used in partly removing the smaller organic particles of suspended matter which cause a rapid decrease of the dissolved oxygen of the streams into which they are discharged; and, for the present purpose, such screens are assumed to have a maximum free opening of not more than $\frac{5}{8}$ in., or 15 mm.

Five types are considered. Several screens, otherwise excellent, but which are cleaned below the surface, are not considered, as this method

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

of cleaning is believed to be fundamentally bad. All the types discussed are in successful operation in Germany, and there are a limited number in England and the United States. These types are:

1.—The Band Screen, exemplified by that at Hamburg, designed by Brunotte and manufactured by the Buckau Machinery Company, of Magdeburg, Germany, and the Carshalton Screen at Sutton, manufactured by John Smith and Company, of Carshalton, England.

2.—The Wing Screen, of Uhlfelder and Schneppendahl, in use at Frankfort, Germany, and manufactured by J. Fries Sohn, of that city.

3.—The Shovel-Vane Screen, in use at Strassburg, Germany, and made by the Geiger Machine Works, of Karlsruhe.

4.—The Drum Screen, designed by G. Windschild, of Dresden-Cossebaude, in use at Trier; and that designed by O. M. Weand, of Reading, Pa., and in use at Brockton, Mass.

5.—The Riensch-Wurl Screen, used at Dresden, and manufactured by Wilhelm Wurl, of Berlin-Weissensee.

To furnish the best results, a screen should be efficient in the removal of material, reliable under conditions to be met in operation, free from nuisance, accessible for repairs, and inexpensive in first cost and operation. In general, the screens described in this paper meet these conditions quite well. Naturally, other things being equal, the finer the screen the more efficient it is, but collected data are so discordant that the desirability of standardizing the methods of obtaining and recording results is made very evident.

It is suggested that special attention be given to the mode of sampling, that samples be weighted in accordance with the flow, and that the amount of preliminary cleaning by coarse screens and grit chambers be always noted.

Except the Hamburg screen, which is somewhat coarser than the others, the fine screens now in regular operation in Germany will ordinarily remove more than 30% of the suspended solids, two-thirds or more of which consist of organic matter. This fact, which is not yet generally recognized in America, places fine screening in competition with tank treatment, although, usually, its efficiency is somewhat less.

In general, fine screening should be considered:

1. Where the removal of all but the very fine solids will furnish a satisfactory effluent;
2. Where land values are so high as to render sedimentation installations costly;
3. Where excavation for tanks would be costly;
4. Where the disposal of sewage sludge would be expensive or cause a nuisance;
5. Where the recovery of grease or fertilizing value is important.

The Removal of Suspended Solids from Sewage.

The discharge of crude sewage into streams is objectionable, primarily, on account of the grosser solids held in suspension or floating on the surface. These are offensive to the eye, and cause foul deposits on river and harbor bottoms, which produce objectionable odors and, by depleting the water of its dissolved oxygen, reduce its capacity to digest the impurities which remain.

Although these dissolved impurities as well as the pathogenic bacteria are left, by far the greater part of the nuisances from sewage effluents are due to the suspended solids. Moreover, where finishing processes are required for the oxidation of the impurities held in solution, or for sterilization, it has been found desirable to remove a part of the solids as a preliminary measure, in order to facilitate these more refined processes. Hence methods of eliminating solids from sewage are of primary importance and are being adopted quite generally by progressive cities.

The two practicable and standard methods of accomplishing this are by allowing the solids to deposit by settling in tanks, from which they are removed at intervals, and by intercepting them by screens. Ordinary sewage in American cities contains about 700 parts per million of total solids, of which 250 parts are in suspension. Of these, some 50 parts per million are so finely divided as to be either colloidal or approaching this condition, and are incapable of removal by ordinary methods. The percentage of suspended matter removable by tank treatment depends on the parts per million in the crude sewage, the length of retention in the tank, the velocity through the tank, and its

design; but, with ordinary sewage and with good design and operation of the tank, one may expect a removal:

With plain sedimentation, of about:
65% of the suspended solids, and
30% of the total organic matter.
With chemical precipitation, of about:
80% of the suspended solids, and
50% of the total organic matter.

It is commonly stated that from 15 to 20% of the suspended matter may be removed by screening, under favorable conditions. It is believed by the writer that the time has come when these figures should be revised; that modern improvements in screen design have reached the point when screening may fairly be compared with tank treatment in the percentage of suspended solids removed; in addition to which it is generally the case that an analysis will indicate a higher percentage of organic matter—or that most objectionable to discharge into streams —per pound of dried solids in screenings than in settled sludge.

Types of Screens.

In general, the screens in use consist either of parallel bars or wires, perforated plates, or woven rods or wires.

Coarse Screens.—Screens of this type are in common use before pumps to protect the valves and prevent the obstruction of water passages. In their simplest form, they consist of a series of vertical or sloping bars, usually from 1 to 4 in. apart, and are cleaned by hand (Figs. 1, 2, and 3). In some large installations the bars form the sides of a cage with a perforated bottom, which is raised by power to an operating floor where it is cleaned by hand. This form is used at the outfall works at Boston, Mass. (Fig. 4). In England, the fixed screen of sloping bars is frequently cleaned automatically by rakes which engage between the bars near the floor of the screen chamber, draw the screenings to the top of the screen, and deposit them on a band conveyor. Still another type of coarse screen is in the form of a basket of interlaced rods through which the sewage passes downward. This screen is raised for cleaning. A preferable form is a rotary screen which is cleaned above water, such as that at the Crossness Outfall Works at London (Fig. 5). In this example

FIG. 1.—COARSE SCREEN AT PROVIDENCE, R. I.

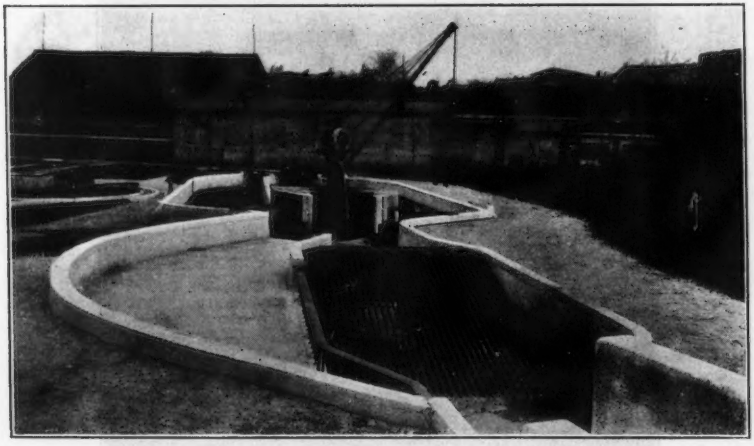

FIG. 2.—COARSE SCREEN AT ESSEN, N. W.

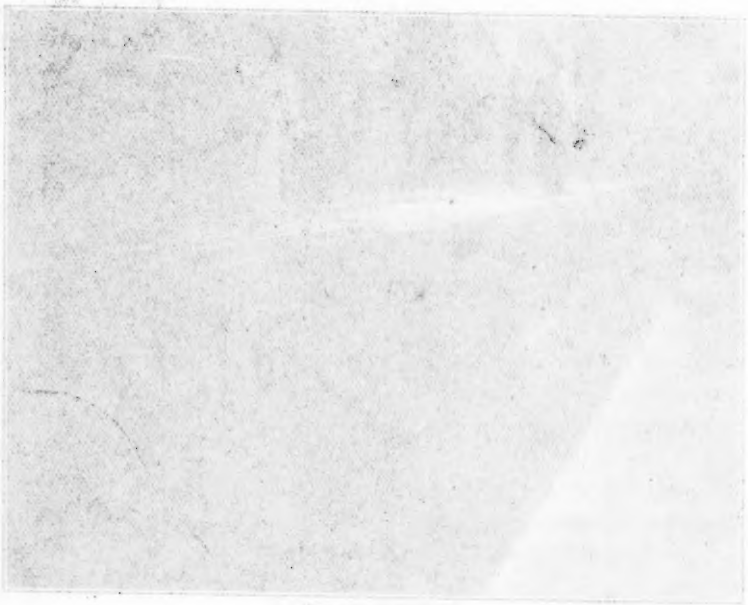

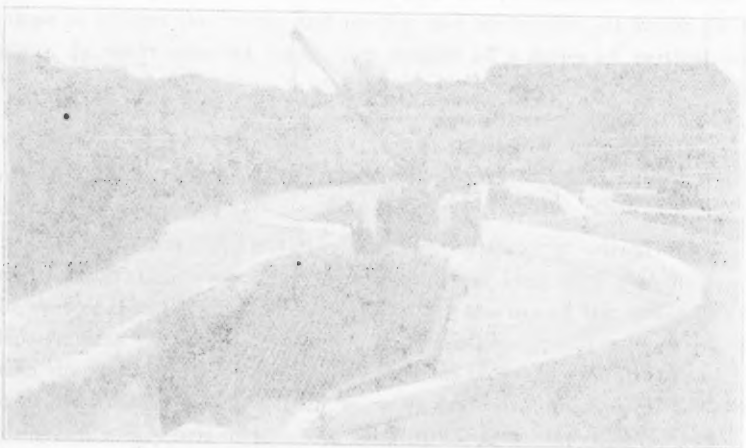

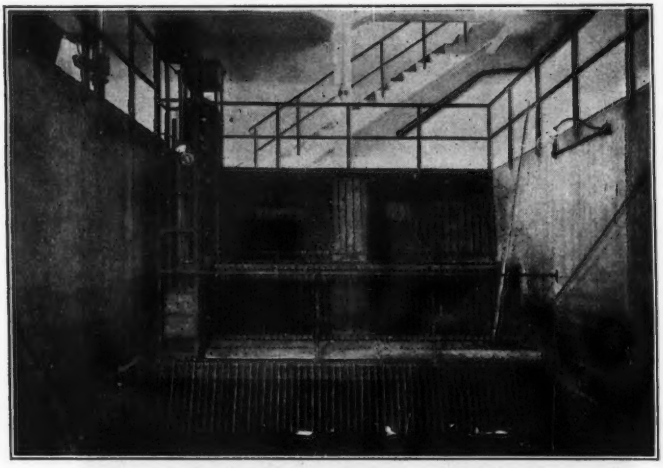

FIG. 3.—COARSE SCREENS AT COLOGNE.

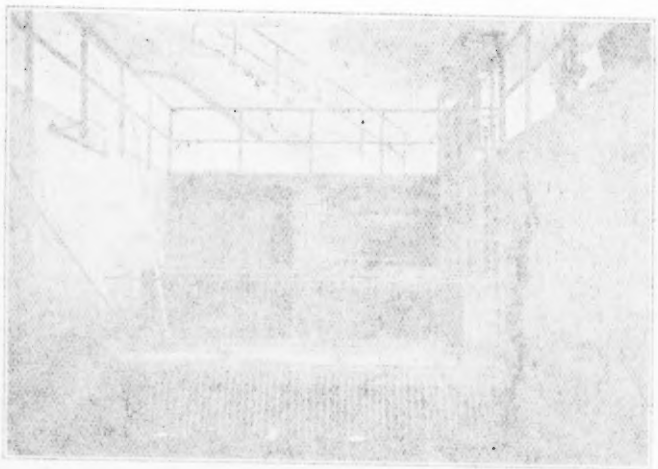
FIG. 4.—CAGE SCREEN AT BOSTON, MASS.



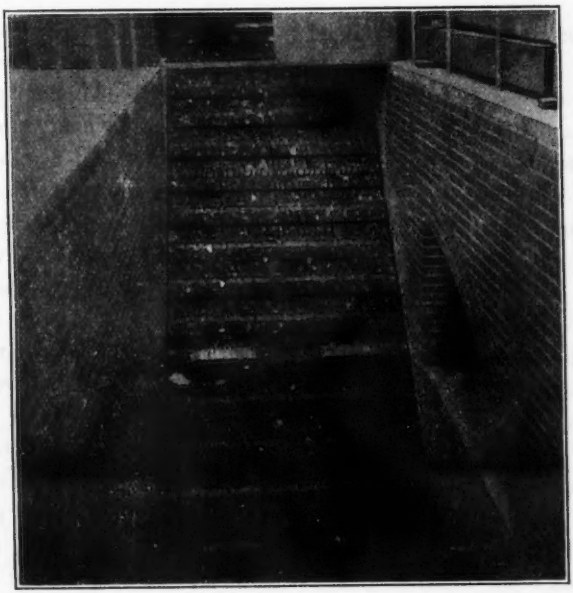


FIG. 5.—COARSE BAND SCREEN AT CROSSNESS, LONDON, ENGLAND.

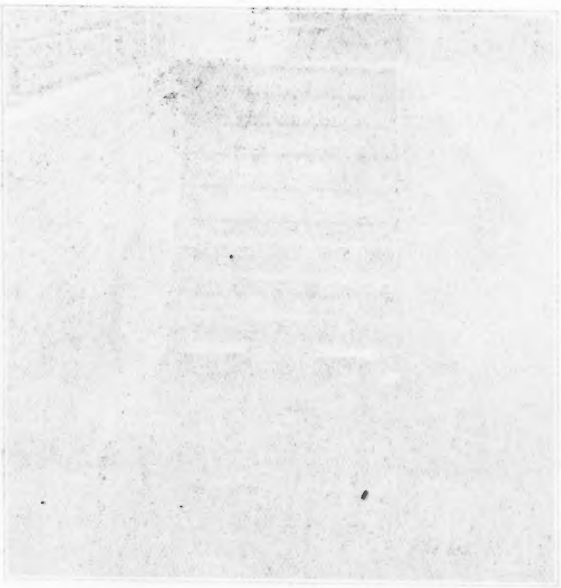
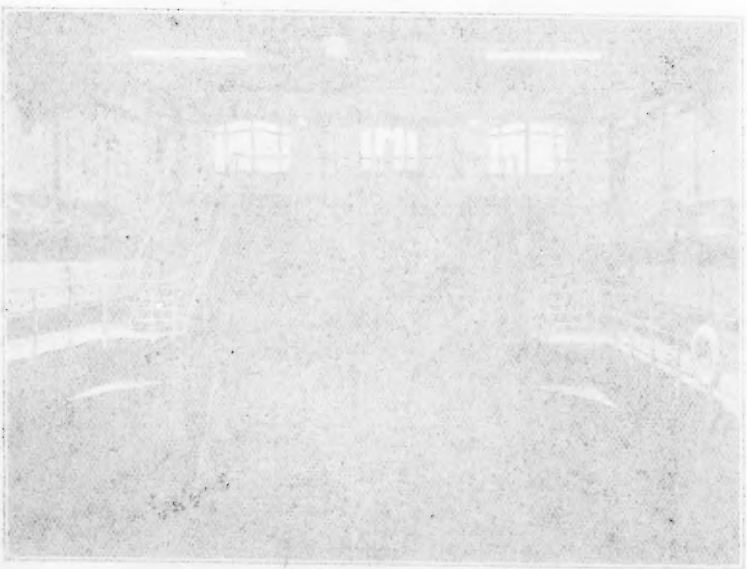
FIG. 6.—BAND SCREEN AT HAMBURG.





grit also is removed by buckets attached to the screen. The spaces in this screen are ¾-in.

According to E. Kuichling, M. Am. Soc. C. E., coarse screens generally remove from 3 to 10 cu. ft. of material per million gallons of sewage, equivalent to about 104 lb. of dried matter or 12½ parts per million of the suspended solids.

Fine Screens.—These screens are in use to a limited extent, both in America and England, but their most marked development has been brought about in Germany. This is perhaps chiefly due to the fact that, though there are many large cities in that country, they are mostly on large streams, such as the Elbe and Rhine, so that, in many cases since 1903, the Government has sanctioned processes which merely retain solids more than 3 mm. in diameter. In such cases, screens may be substituted for the more expensive tank installations. The result has been an introduction of several types of fine screens in many towns during the past few years.

It is not easy to draw a definite line between fine and coarse screens, but, for the present discussion, we may consider those having a clear opening or mesh not greater than 0.6 in., or 15 mm. as "fine".

From experiments by Monti at Berlin, it was concluded*

"that most of the suspended matter in sewage is usually in a very fine state of division, or capable of passing through a sieve having meshes 0.02 inch square; that most of the solid fecal matter found in the liquid can be arrested on a sieve having meshes 0.25 inch square; and that a sieve with meshes 0.10 inch square is probably fine enough to extract from the sewage all suspended matter of appreciable magnitude, and especially such as is likely to become offensive [under conditions proposed for Rochester]. * * * It is believed, * * *, that ample evidence has been submitted to show that a surprisingly large quantity of offensive organic matter can be extracted from sewage by properly designed screening appliances, and that the screened liquid may then be admitted safely for final disposal into bodies of water which would soon become repulsive without such screening."

Function of Fine Screens.

The function of fine screens is quite different from that of coarse ones, so that we may be justified in considering them in a class by themselves, presenting problems of design and operation that have no similarity to the design or operation of coarse screens. The

* Sewage Disposal System. Rochester, Kuichling, 1913.

use of fine screens may be advisable for any of the following purposes:

1. The removal of matter that otherwise would cause the pollution of the stream receiving the effluent;
2. The removal of solids that otherwise would cause the frequent subsequent clogging of sprinkler nozzles or filters; and
3. The removal of material likely to promote the formation of scum in subsequent tank treatment.

In Germany their use has been justified mainly for the first reason, but it is recognized that fine screening before applying sewage to sprinkling or sand filters may cause a marked reduction in operating expenses. In Baltimore fine screens have been placed between the tanks and sprinkling filters, with the result that whereas, previously, "two men, eight hours per day, were always required and sometimes more for cleaning nozzles for between six and nine acres of filter area, with the screen in operation two men are required to spend about two hours a day each for the same number of nozzles."*

According to the Massachusetts State Board of Health: "When practically all the suspended matters were removed from the sewage the possible rate of filtration [to sprinklers] could be doubled."†

On the other hand, their use for this purpose has been discontinued at Birmingham, England, and at Atlanta, Ga., as unnecessary after efficient tank treatment. On the whole, it is questionable whether their expense is often justifiable for this purpose. Mr. Francis E. Daniels‡ states that "the use of fine screens will entirely prevent the formation of tank scum." If this is substantiated by further experience, it will be an argument in their favor in connection with those sedimentation plants where the formation of scum has been found to be a nuisance.

Conditions to be Satisfied.—The conditions to be satisfied in a fine screen may be summarized as follows:

a. It must remove a sufficient quantity of the suspended solids and total organic matter in regular operation to satisfy the

* Letter from H. C. McRae, Assoc. M. Am. Soc. C. E., Division Engineer, Baltimore Sewerage Commission, February 24th, 1914.

† *Surveyor and Municipal and County Engineer*, March 6th, 1914.

‡ Director, Water and Sewerage Inspection, State Board of Health, New Jersey, *Municipal Journal*, January 15th. 1914.

needs of the situation. In other words, its efficiency must be adequate.

b. In operation, it must be reliable; and, in capacity, it must be ample, under the conditions of sewage flow and surface elevation which may obtain.

c. Its operation must be free from nuisance and unsanitary conditions.

d. All parts must be accessible for inspection, repair, and renewal.

e. The cost of installation must be low.

f. The costs of operation, renewals, and repairs must be low.

These conditions will be considered subsequently, in their relation to different screens, under the heading, "Comparison of Screens."

Types of Fine Screens.

The fine screens in successful operation may be classified under five distinct types, all of which are found in Germany. In all of them the screenings are raised gently above the surface before being removed, instead of being raked off while submerged, as is done with some of the coarser screens in England, and at Paris, Cologne, and elsewhere.

These types are as follows, in the order of the usual size of their opening (Fig. 7)*:

1. The band screen (*Abfischgitter*), consisting of an endless flexible band, either of wire mesh or links, which passes over upper and lower rollers.

2. The wing screen (*Klärrechen*), formed of vanes, as in a paddle-wheel, which are composed of radial bars at uniform distances apart.

3. The shovel-vane screen (*Siebschaufelrad*), similar to the wing screen, but with semicircular wings and a different method of removing the screenings.

4. The Riensch-Wurl screen (*Separatorscheib*), which consists of a perforated disk surmounted by a truncated cone, also perforated. The disk is mounted on an inclined shaft.

5. The drum screen (*Siebtrommel*), consisting of a cylinder or cone of perforated plates or wire mesh, which rotates on a horizontal axis.

* Except that the wire mesh used in any type may be very fine.

The fourth and fifth may have openings of 1 mm. or less. Descriptions of each, with typical example, are given.

Band Screens.

Band screens may be broadly divided into two classes: (*a*) those composed of bars or links; and (*b*) those composed of a fine mesh.

a.—Hamburg.—The Hamburg screen (Fig. 6) at the main outfall works on the north side of the Elbe, is composed of a series of parallel links, 14.2 in. (36 cm.) long, 0.2 in. (0.5 cm.) thick, and

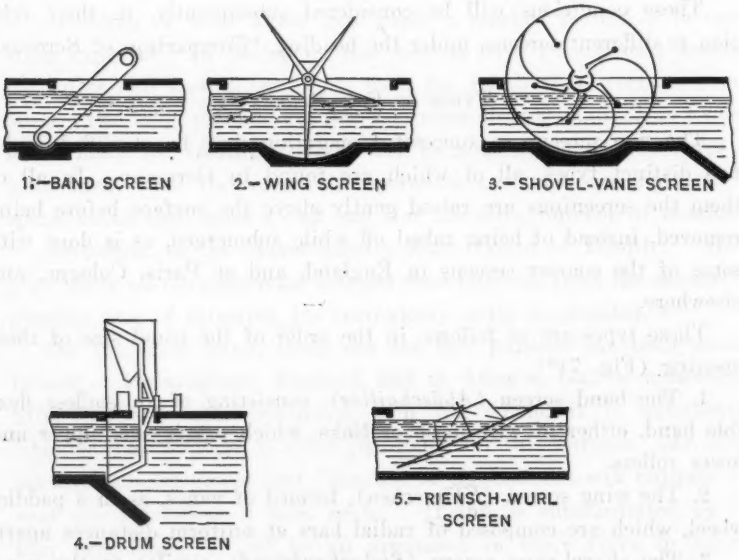


FIG. 7.

0.59 in. (15 mm.) apart. These links were first made of hard rubber, but are now being made of aluminum alloy, the essentials being a material of sufficient strength, not readily corroded, and not too heavy. There are some 14 000 links in the screen. They are assembled in sections which are held together by angle-iron frames, 9.85 ft. (3 m.) long and 15 in. (38 cm.) wide, of which there are forty-six in each of the two screens installed. The bars are readily removable from the frames for purposes of repair.

Each of the two screens at this station is about 33 ft. (10 m.) long, 10.8 ft. (3.3 m.) wide, and 19 ft. (5.8 m.) high, over all. Their inclination to the horizontal is about 63 degrees. This great length has been made necessary by the tidal range of 6.2 ft. to which the screens are subjected. They are supported and operated by wheels resting on rails, on each side, which pass over sprocket wheels mounted on a shaft at each end, the upper shaft being connected by gearing to an electric motor.

As the assembled frames of links forming the screen band move upward with a velocity of from 1 to 2 in. per sec., they carry with them, above the surface of the sewage, the material intercepted. As larger particles of material are caught, they serve to prevent the passage of much that is less in size than the clear space between the links. At times paper becomes plastered over the links, and backs up the sewage as much as 28 or 30 in. (70 to 75 cm.), instead of some 8 in. (20 cm.), the usual head. For this reason the screen is designed to resist this occasional horizontal thrust. The ordinary depth on the screen is about 6 ft.

Back of the screen, near the top, hangs a frame to which are attached at right angles the prongs of a comb scraper or rake; these enter the spaces between the links intermittently and remove the screenings. By a contact with an electro-magnet, this frame swings back after cleaning a section of the screen, and the screenings are scraped off automatically to a band conveyor by the edge of a plain, hard-rubber scraper. The frame then swings forward again and repeats the operation with the next section of screen.

For convenience in making repairs, the entire screen can be swung up above the sewage by a chain attached to its lower edge.

About 2½ h.p. is required in the ordinary operation of the screen, and 2½ h.p. more for the cleaning device. The station contains two 30-h.p. generators, which furnish current for the following motors:

Bucket elevator in grit chamber	4.	h.p.
Swinging the bucket elevator in grit chamber	4.6	"
Screen and belt conveyor	3.	"
Inclined screw conveyor	4.5	"
Bucket elevator for screenings	1.75	"
Ventilator	3.	"

In addition, current is furnished for 4 arc lamps, 74 incandescent lamps, and for feeding a storage battery used for the illumination of boats in the main outfall sewer.*

The population now tributary to the works is about 1 000 000 and the sewage flow is 53 000 000 gal.† (190 000 cu. m.) per day. This varies from 140 cu. ft. per sec. (4 000 liters per sec.) during dry weather to 700 cu. ft. per sec. (20 000 liters per sec.) during storms.

On entering the station the sewage first flows through a grit chamber, 54 ft. long, 30 ft. wide, and about 6½ ft. deep below the normal surface of the sewage. About 9 cu. yd. (7 cu. m.) of sand and other heavy material are removed per day here, or 0.17 cu. yd. per million gallons.

From the grit chamber the sewage passes through the screens. These take out 18 cu. yd. (14 cu. m.) per day or 0.34 cu. yd. per million gallons of sewage. It then flows through tide-gates to three riveted-steel outlet pipes, 6.56 ft. (2 m.) in diameter, and 230 ft. (70 m.), 328 ft. (100 m.), and 436 ft. (133 m.) long, respectively, from which it is discharged near the bottom of the Elbe.

Operation is suspended for about 2½ hours during each high tide, or 5 hours per day, as the surface of the river is then higher than that of the sewage, causing the tide-gates to close.

The grit and screenings are carried by scows, having a capacity of 90 cu. yd. (70 cu. m.), 19 miles down the Elbe to the Island of Waltershof, where they are removed by farmers and used to fertilize land, on payment of 7 cents per cu. yd. by the city.

TABLE 1.—Composition of Grit and Screenings from Hamburg Screens.

Analysis No.	Grit.			Screenings.		
	1	2	3	1	2	3
	%	%	%	%	%	%
Water	65.35	55.90	22.87	83	92.62	85.24

† 190 000 cu. m. from 950 000 population in 1910, "Die Stadtische Abwasserbeseitigung in Deutschland," Salomon, 1910, Vol. III, p. 230.

Table 1 shows the composition of the grit and screenings, as given by Merckel.

From analyses of five samples of mixed detritus of varying character from the grit chamber and screens, Dr. Gillmeister, City Chemist, has estimated the value of the contained nitrogen and phosphoric acid as fertilizer, as given in Table 2.

TABLE 2.—VALUE OF CONTAINED NITROGEN AND PHOSPHORIC ACID AS FERTILIZER.

Sample No.	Percentage of moisture.	Percentage of N in dried material.	Percentage of P_2O_5 in dried material.	Percentage of grease in dried material.	Value of Dried Material.		Description of material.
					In dollars per ton.	In Marks per 100 kg.	
I	92.62	3.69	2.34	22.85	$16.87	7.81	Loose; lumpy; somewhat plastic, sticky; fecal odor.
II	22.87	0.27	0.52	0.57	1.62	0.75	Blackish; sandy; mixed with particles of wood and coal.
III	55.90	0.61	0.67	2.91	3.09	1.43	Blackish; sandy; fine; odor slightly fecal.
IV	85.24	0.10	0.72	34.63	1.16	0.54	Loose and fibrous; slightly sandy; slight odor.
V	59.79	1.06	0.83	1.98	5.03	2.33	Rather loose, sandy; dusty.

When mixed with four parts of street sweepings, the grit and screenings are disposed of by incineration.

The first cost of this plant is given by Merckel as follows:

Foundations, etc.	$174 000
Screen house	10 500
Machinery	33 300
Storage house at dock	2 900
Outlet pipes	53 500
Total	$274 200

Up to the present time, it has cost about $300 000.

These screens were designed by Brunotte, and are manufactured by the Buckau Machine Fabrik, of Magdeburg-Buckau.

Four similar screens, although only about 6 ft. (1.8 m.) wide and with 0.4-in. (10-mm.) spaces between the links, have been installed more recently on the south side of the Elbe. These are

operated by Diesel motors, and require only about 1 h.p. each. The present population tributary to this plant is about 10 000, increased during the day by 20 000 workmen who live on the north side of the river.

The grit chamber and screens together remove about 11.7 cu. yd. (9 cu. m.) of material daily, one-third of which is organic, indicating a higher efficiency than in the older works. This is probably due in part to a lower velocity (4 in. = 10 cm. per sec.) in the grit chamber than at the North station (19.7 in. = 50 cm. per sec.).

The South Hamburg station is designed to care for three times the present flow.

b.—Göttingen.—Other band screens, in which a wire mesh takes the place of links, are used in a number of places. There are two such at Göttingen, installed in 1903, which will serve as an illustration.

Here the bands are 55¾ ft. (17 m.) long, and are set at an angle of 55° with the horizon. They are composed of 0.06-in. (1½-mm.) copper wire, twisted spirally, and woven with a 0.4-in. (10-mm.) mesh, which passes over two drums, 20 in. (50 cm.) in diameter. The upper drum is belt-driven from an undershot wheel, and the lower one is placed in a sump, 28 in. (70 cm.) deep. Brass angles are attached to the screen, 3.3 ft. (1 m.) apart, to catch matter tending to roll back into the sewage. The screen is cleaned by a brush and water jets.

The material is delivered to a tip-wagon having a double interior screen on one side for draining off the moisture, and is then composted with peat dust and sweepings for a fertilizer.

In operation, the screen moves with a velocity of about 8 ft. per min. (4 cm. per sec.)

The lower end of the screen can be raised above the surface, as at Hamburg, for inspection and cleaning. It is also lifted at night when a 2-in. (5-cm.) bar screen above is lowered to take its place.

As the band stretches, it has been found necessary to tighten it from time to time. This results in a slight narrowing, so that wooden fillers are inserted to prevent leakage between the screen and the sides of the channel.

Every 5 or 6 weeks the screens require a thorough cleaning, and the sediment that has collected in the channels is flushed out.

As Göttingen is sewered by the separate system, grit chambers have not been found necessary. In 1907, when the population was 35 000, 38% of the houses were supplied with water-closets. The screenings amounted to 10.3 cu. yd. (7.9 cu. m.) per 100 population.* The screenings per 1 000 population per day were, therefore, $\frac{103}{365} = 0.282$ cu. yd. The sewage flow was then about 2 600 000 gal. per day,† so that about 3.8 cu. yd. were removed per million gallons. The suspended matter is said to have been reduced 90 per cent. The total cost of the works was $18 500 (60 700 Marks), of which the screens and machinery cost $3 600 (15 000 Marks). The screens were installed by City Engineer Hertzberg.

There are two other fine band screens to be mentioned.

The Carshalton Screen.—This screen (Fig. 8) is similar in principle to those at Göttingen, but the slope is not so great—usually 30° with the horizon—and it is "made of perforated steel strips, twisted steel wires and pins, similar to a coal picking belt. The holes are usually $\frac{3}{8}$ in. in diameter." It is operated by an undershot wheel placed behind the screen.

These screens are installed at Birmingham, Chester, Croydon, Wrexham, Ipswich, and about a dozen more English towns, generally between tanks and oxidizing beds. They are manufactured by John Smith and Company, of Carshalton. According to the manufacturers, they will remove about $2\frac{1}{2}$ cu. yd. of material per million U. S. gallons of sewage, varying, of course, with the character of the latter. A screen with a 6-ft. width will care for about 2 750 000 U. S. gal. in 24 hours. At Sutton, one of these screens, with a $\frac{1}{4}$-in. mesh, removes 1 200 lb. of screenings per million gallons.‡

The Jennings Screen.—This screen (Fig. 9) consists of a fine wire-mesh band, and has been in operation since July, 1913, at the Chicago Stock Yards, with a flow of from 1 250 000 to 1 500 000 gal. per day. Although this may be said to be still in the experimental stage, a brief reference to it will not be out of place. The wires are of Monel metal, with 40 meshes per inch. The screen is composed of separate sections of removable frames, for convenience in

* Based on the weight of screenings, assuming their specific gravity to be 1.1.

† 2 200 000 gal. per day from 30 000 persons in 1905, E. Kuichling, *Proceedings*, Fourth Annual Meeting, New Jersey Sanitary Association, 1908.

‡ Sewage Disposal System, Rochester, N. Y., E. Kuichling, April, 1913.

repairs and renewals. The screenings are blown off by air compressed to 1½ lb. per sq. in. at the slotted jet used for cleaning. A 10-h.p. motor is used for operating the screen and blower, although less power is required after starting. The entire cost for air and power amounts to from 12 to 15 cents per hour. The plant is looked over once or twice a day by one of the regular employes so that there is no extra charge for attendance.

According to C. A. Jennings, Assoc. Am. Soc. C. E., the designer, "with an influent running about 700 p.p.m. suspended matter, the screen removed about 63% * * *. The screenings contained an average of about 79% moisture."

In one test of 6 hours' duration, the wet screenings amounted to 6 186 lb. per million gallons. Another test of 5 hours gave 4 828 lb. per million gallons, the suspended matter in this case being 20% lower than in the former.

Features of this screen are the fineness of the mesh and its construction in sections, as at Hamburg.

Wing Screens.

Frankfort.—Three screens of five vanes each are installed at Frankfort (Fig. 10). The vanes are 6.56 ft. (2 m.) wide and 9.84 ft. (3 m.) long, measuring from the center of the shaft. The effective radial length is 8.2 ft. (2.5 m.). Each vane consists of 0.16 by 1.20-in. (4 by 30-mm.) steel bars, 0.4 in. (10 mm.) apart. These bars are assembled in two sections, 3.28 ft. (1 m.) wide, and are tied together by nine transverse rods. On these rods filler rings alternate with the bars to preserve the proper spacing, and, by changing the size of these rings, the spacing may be altered. The ratio of the free opening to the entire vane is 1 : 2.4. To avoid undue friction in the passage of the sewage through the screen, these bars are given a less depth between the holes for the tie-rods.

The rectangular channel is depressed at the screen, so that during a revolution one vane will occupy the entire cross-section of the stream at all times and prevent the by-passing of an appreciable quantity of sewage.

As the lowest vane, moving against the current, rises slowly, a hard-rubber scraper, hung by a long arm at each end, is forced by the motion of the vane to travel from its inner portion near the

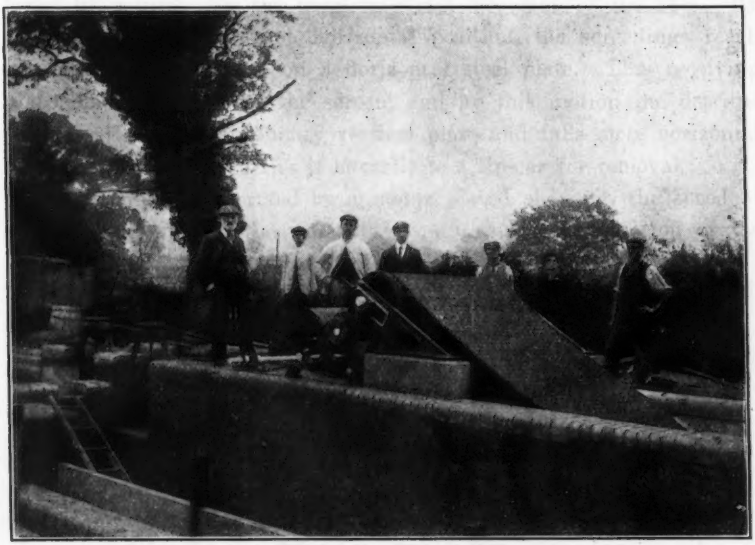

FIG. 8.—CARSHALTON SCREEN, AT WREXHAM, ENGLAND.

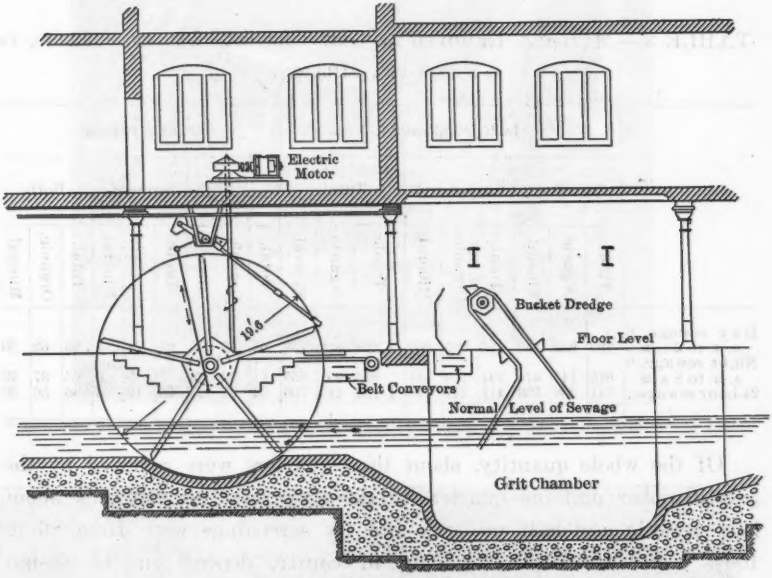
FIG. 9.—THE JENNINGS SCREEN.

shaft to the extremity of the bars. This scraper is, or may be, followed by a brush for the more thorough cleansing of the bars. By the time the vane is in a horizontal position, the screenings reach its outer edge and drop on a horizontal steel plate. This receiving plate then recedes from the screen, and by this motion the detritus is scraped off by a stationary vertical plate and falls on a horizontal belt conveyor. This carries it laterally to a tip-car for removal.

Each screen is operated by a motor placed above it, the speed of which is adjusted to the work to be performed. The motion of the



WING SCREEN AT FRANKFORT

FIG. 10.

receiving plate is transmitted by mechanism from the scraping apparatus, so that it occurs at precisely the time required. The belt conveyor has a velocity of 3¼ ft. (1 m.) per sec.

The sewerage of Frankfort is on the combined system, and the population is about 420 000. The volume varies from 21 000 000 to 26 000 000 gal. (80 000 to 100 000 cu. m.) per day. The daily per capita flow, therefore, is about 56 gal. (213 liters).

After passing a grit chamber, where 20 tons of detritus are removed daily, or, say, 0.8 ton per million gallons, the sewage flows

through the screens, two of which are generally in use. They remove automatically 50 tons of screenings per day, or 2 tons per million gallons of sewage, composed largely of feces and paper.

Measurements made about 7 years ago indicate that 16% of the suspended matter is removed in the grit chamber and 10% more by the screens, making 26% in all. At that time the water supply was 47 gal. and the sewage flow 39½ gal. per capita. Table 3 shows the quantities of material removed by the grit chamber and the screens, as given by Uhlfelder and Tillmans.*

TABLE 3.—MATERIAL REMOVED BY GRIT CHAMBER AND BY SCREENS, IN PARTS PER MILLION.

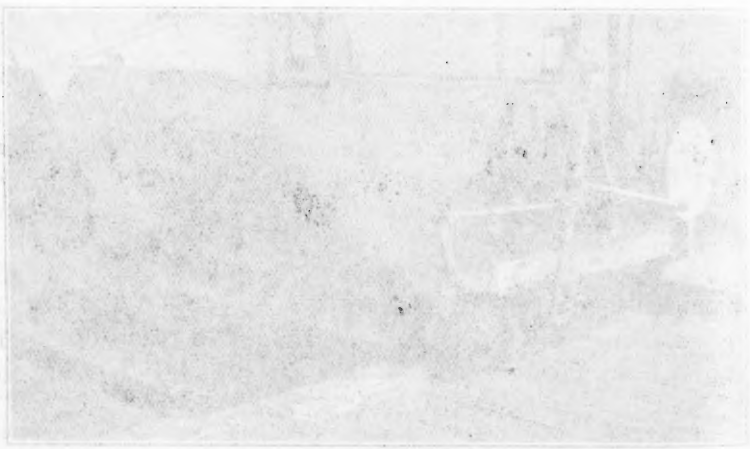
Of the whole quantity, about three-quarters were removed by the grit chamber and one-quarter by the screens. The grit was about half organic and half mineral, and the screenings were from 86 to 100% organic. These relations, of course, depend on the design and operation of both grit chamber and screens; but, at Frankfort, although the grit chamber removes three times as much material as the screens, the latter remove half the organic matter taken out. To operate one of these screens requires 2.3 h.p.

During eight years of service, the repairs and renewals are said to have been insignificant. The annual cost of operation is given by the late City Engineer Koelle as 1.1 cents per capita. It is otherwise stated as 18 cents per cu. yd. (0.75 Mark per cu. m.) of screenings, or about one-sixth of the cost when removed by hand.

*"Die Frankfurter Klaranlage," *Wasser und Abwasser*, Vol. 1, No. 7, 1909. *Mitteilungen a. d. Königl. Pruf. für Wasserversorgung und Abwasserbeseitigung*, Vol. 10, 1908.

FIG. 11.—WING SCREEN AT ELBERFELD.

FIG. 12.—WING SCREEN AT BRADFORD, ENGLAND.



Elberfeld.—At Elberfeld there are two screens (Fig. 11), similar to those at Frankfort, taking the sewage from a population of about 340 000 persons in Elberfeld and Barmen. The sewers are mostly on the separate system, and the volume of sewage is 16 000 000 gal. (60 000 cu. m.) daily. It contains 500 parts per million of suspended material.

The sewage is quite fresh when received at the works. It first enters a grit chamber where two dredges take out the coarse material—largely kitchen refuse, with a little sand. It then passes the screens. These rotate once in 3½ min. and, with the grit chamber, remove 18.2 cu. yd. (14 cu. m.) of material per day, or 1.15 cu. yd. per million gallons. As at Frankfort, these appeared to consist chiefly of feces and paper. They are placed in unprotected dumps for drying, and are naturally very offensive in warm weather.

The screens are cleaned about once a week, while in operation, by raking out the bars by hand. This takes one man about ½ hour for the two screens.

The power required for operating a grit elevator, a sludge pump, and the screens is usually 5 h.p., but, for short periods, may be as much as 10 h.p.

The Elberfeld screens are placed before settling tanks, the excuse for this preparatory treatment being the removal of a substantial part of the solids in a form containing relatively little moisture and, therefore, readily handled.

At the works of J. S. Fries Sohn, at Frankfort, where the Frankfort and Elberfeld screens were manufactured, the writer was told that one such screen would ordinarily remove 16 cu. yd. (12 cu. m.) of material from 8 000 000 gal. of sewage (30 000 cu. m.) per day, or 2.0 cu. yd. per million gallons, and that for operating the screens 3 h.p., or, with auxiliary machinery, 5 h.p., would be required.

Bradford, England.—Two screens of the Frankfort type were installed at Bradford a few years ago, but differ from the former in some details (Fig. 12). Each is 6 ft. 2½ in. wide, with length of vane of 4 ft. 11½ in. and a capacity of 3 500 000 gal. per day. The bars are about ¼ by 1 in. in section, and ½ in. apart. There are no cross-rods except near the extremity of the vane. A chief function of these screens is to intercept wool fiber, which occurs in considerable quantity in the Bradford sewage. For this purpose the wing

screen has proved well adapted. In operation, the screen comes to rest when a pair of vanes reaches the horizontal position, and a rake with teeth interlocking with the screen bars is introduced and withdrawn mechanically, removing the material intercepted. A few fibers clinging to the cross-rod occasionally require removal by hand. For each one-sixth of a revolution 33 sec. are required, and an equal interval for cleaning.

Wiesbaden.—At Wiesbaden a screen of this type, with six vanes, was put in by Schneppendahl in 1899. The vanes are 6.56 ft. (2 m.) wide, and the bars are 0.6 in. (15 cm.) apart. It is operated by hand, day and night. The sewage amounts to about 3 000 000 gal. (11 000 cu. m.) daily from 100 000 persons, is domestic in character, and contains much soap and fats. It first passes a fixed screen with 1.6-in. (40-mm.) spaces. The fine screen removes 3.4 cu. yd. (2.6 cu. m.) of screenings, largely feces, or 1.1 cu. yd. per million gallons.

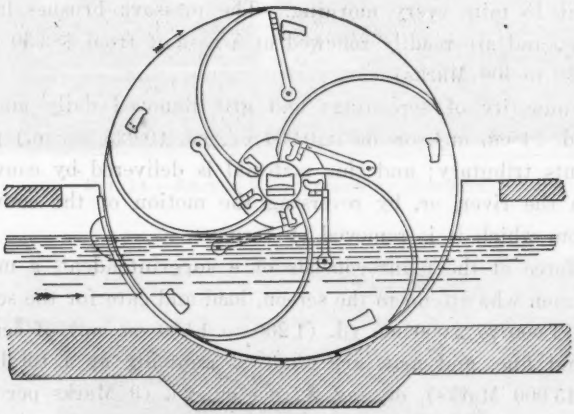
The Shovel-Vane Screen.

A very ingenious modification of the wing screen is that known as the *Siebschaufelrad,* patented and manufactured by the Geiger Manufacturing Company, of Karlsruhe (Fig. 13). In this screen there are five semicircular vanes between two circular plates which form the sides of the apparatus. The axle is hollow, with the top third open, and contains a belt conveyor. Owing to the shape of the vanes, which are nearly tangent to the circumference of the side plates on their outer extremities and to the radius at their inner edges, the sediment and floating matter are scooped up gently above the surface of the sewage, with little loss or disintegration, and finally drop by gravity from the screen to the belt conveyor. Such material as adheres to the vanes is brushed off mechanically when above the axle by a brush on the end of an arm swinging from a center near the middle of the adjacent vane. This brush is of piassava fiber, which is well adapted to the purpose. By a mechanical device it comes into contact with the vane only while swinging in an inward direction over the part of the vane above the axle. At other times, it rests near the axle, and, therefore, is ordinarily above water. In the operation there is little tendency to crush the screenings or press them through the screen itself.

The screen vanes are of pressed wires of V-section, and are 1, 2, or 3 mm. apart, and held in place by a central rib and by round transverse tie-rods.

Power is transmitted to the wheel by gearing. The motion is slow and uniform. The moving parts are open to inspection and repair above the level of the sewage.

Paper, which might partly clog the screen and obstruct the flow, is retained by a baffle placed before the screen, but sand or gravel which may pass the grit chamber above is handled and removed with the other screenings. There is a clearance of only 0.04 in. (1 mm.)



GEIGERS SHOVEL-VANE SCREEN

FIG. 13.

between the screen and the curved bottom of the channel, and this space is prevented from clogging by the constant motion of the screen against the current.

Shovel-vane screens are in operation at Strassburg and Gleiwitz, Germany, and at Temesvar, Hungary.

Strassburg.—A population of 160 000 contributes daily 11 900 000 gal. (45 000 cu. m.) of rather weak domestic sewage containing trade wastes from the city and the suburbs, Neudorf, Kronenburg, and Königshofen-Gruneberg. It arrives while quite fresh, and first passes two vertical screens of bars 0.32 in. (8 mm.) apart, which are cleaned by a movable scraper.

Below these bar screens a Geiger screen was put in as an experiment in August, 1908, with 0.10-in. (2½-mm.) openings and a width of 5.25 ft. (1.6 m.). Having been erected in an old grit chamber, the ratio of submergence to depth of sewage is said to have been unfavorable for the best results, the diameter too small, the axle too low with reference to the surface, and the free opening too small, considering the width of the channel above, which is 9.2 ft. (2.8 m.).

Nevertheless, the capacity of the screen, with the sewage backed up 12 in. (0.3 m.), is about 18 000 000 gal. per day (800 liters per sec.). The small quantity of hair and paper which collects on the screen is removed by a jet from a hose operated by a plunger pump for about 15 min. every morning. The piassava brushes last about 2 months, and are readily renewed at a cost of from $83.50 to $95.00 (from 350 to 400 Marks).

The quantity of screenings and grit removed daily amounts to 5¼ cu. yd. (4 cu. m.), or about 0.034 cu. yd. (0.025 cu. m.) per 1 000 inhabitants tributary; and this material is delivered by conveyors to scows in the river, or, by reversing the motion of the conveyor, to a pit from which it is removed by farmers.

The force at the plant consists of a superintendent, a machinist, and two men who attend to the screen, load and care for the scows, etc.

From 1 600 to 2 000 cu. yd. (1 200 to 1 500 cu. m.) of screenings, coarse and fine, and grit, are removed annually at a total cost of $3 570 (15 000 Marks), or, say, $2 per cu. yd. (9 Marks per cu. m.).

The cost of operation of the fine screens, exclusive of labor, is 30 cents (1.25 Marks) per 10-hour day, and the power consumed is 25 kw.

About 1.3 cu. yd. (1 cu. m.) of fine screenings are removed per day from the sewage of 30 000 persons, at a cost of 5.4 cents per cu. yd. (0.30 Mark per cu. m.).

Gleiwitz.—The population of Gleiwitz is about 67 000, and produces a volume of sewage varying from 1 000 000 to 2 600 000 gal. (4 000 to 10 000 cu. m.) per day. Two Geiger screens (Fig. 14), 12.5 ft. (3.8 m.) in diameter and 5.9 ft. (1.8 m.) wide, are installed. The screen vanes are composed of V-shaped rods, 0.12 in. (3 mm.) apart. The quantity of material removed per year is 4 700 cu. yd. (3 600 cu. m.), or 0.19 cu. yd. per 1 000 persons daily, at an annual cost of from $480 to $710 (2 000 to 3 000 Marks). The cost, therefore, is

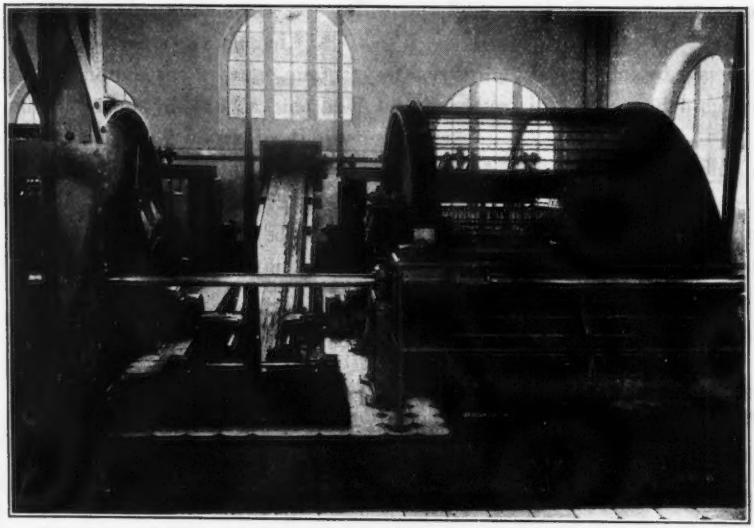


FIG. 14.—SHOVEL-VANE SCREEN AT GLEIWITZ.

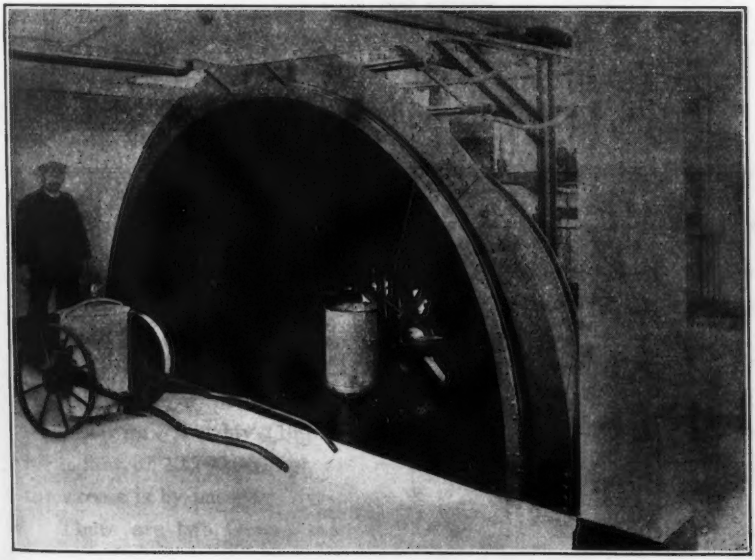

FIG. 15.—DRUM SCREEN AT TRIER. FRONT VIEW.

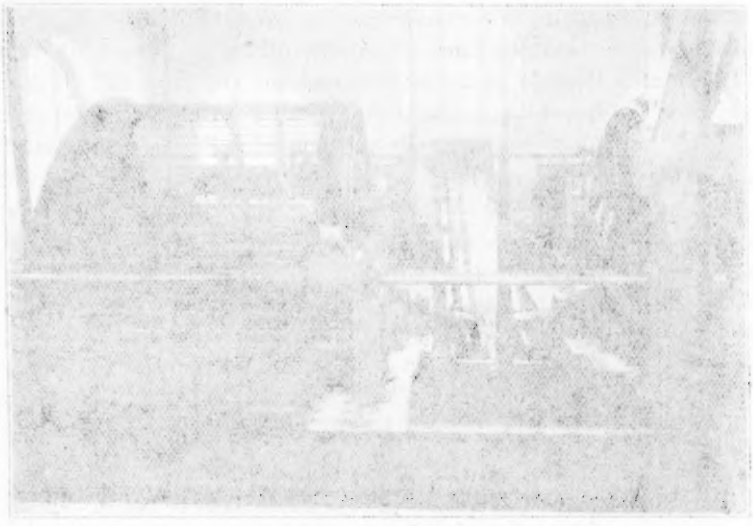


probably about 90 cents per million gallons, and the cost of screenings, 12½ cents per cu. yd.*

Although the average quantity of screenings is 12.9 cu. yd. per day, about 21 cu. yd. (16 cu. m.) have been removed in 1 day, and 5 cu. yd. (4 cu. m.) in 2 hours, by the two screens.

The cost of each screen was $2 800 (11 750 Marks), and that of the entire plant $6 860 (28 800 Marks).

Two men are required to attend the screens and pumps, one during the day and one at night. The power for operation varies from 1 to 2 h.p.

Analyses of the sewage before and after screening are given in Table 4.

TABLE 4.—ANALYSES OF SEWAGE AT THE GLEIWITZ SCREENING PLANT, IN PARTS PER MILLION.

	Before screening.	After screening.
Reaction	Weakly alkaline	Weakly alkaline.
Appearance	Brown, strong, with coarse material; turbid, with light settleable particles.	Yellowish brown, turbid, with fine suspended matter.
Suspended solids	2 112.8	785.2
Dried residue after filtration	1 237.2	1 260.4
Loss on evaporation	400.0 = 33.08%	388.8 = 30.85%
Oxygen consumed	105.5	100.6
Ammonia	30.0	30.0
Chlorine	262.2	279.4
Sulphuric acid	Present.	Trace.
Nitrous acid	None.	None.
Nitric acid	None.	None.

The clarifying efficiency, therefore, was $\frac{2\,112.8 - 785.2}{2\,112.8} = 62.9\%$; on the other hand, the solids in solution (probably colloidal matter) increased from 1 237.2 to 1 260.4 parts per million, or about 1.9 per cent.

Temesvar.—The tributary population at this place is about 60 000, and the rate of flow through the screens varies from 3 650 000 to 9 150 000 gal. per day (160 to 400 liters per sec.). Provision is made for a flow of 13 700 000 gal. per day (600 liters per sec.), beyond which the excess is by-passed.

There are two Geiger screens, 11.8 ft. (3.60 m.) in diameter and

* *Gesundheits-Ingenieur*, December 21st, 1912.

5.25 ft. (1.60 m.) wide. As at Gleiwitz, the free opening is 0.12 in. (3 mm.). Only one screen is operated at a time.

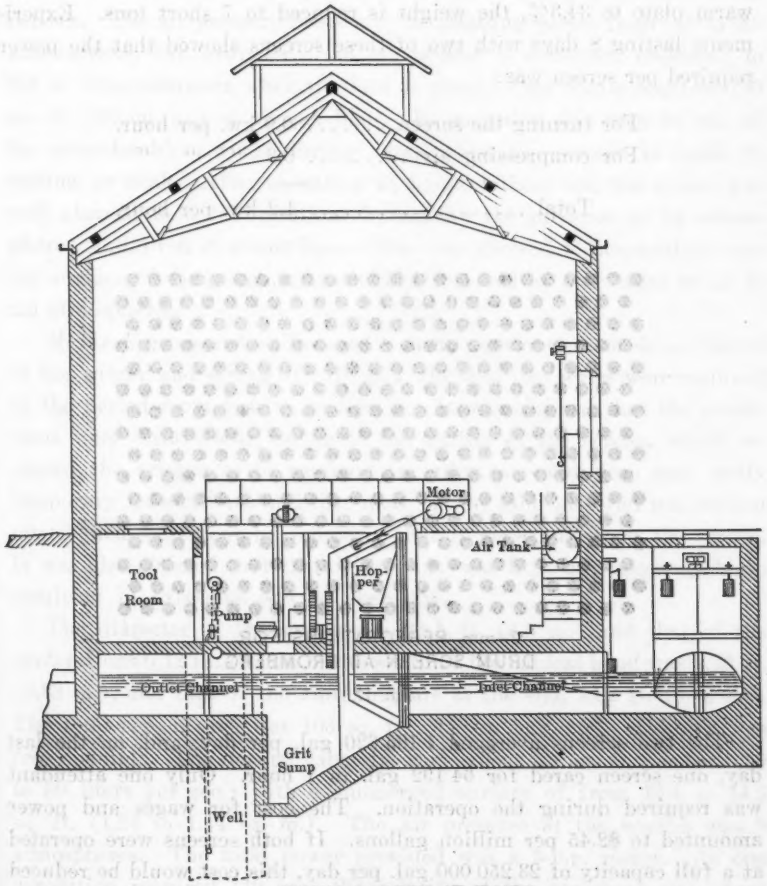
From 4 to 8 cu. yd. (3 to 6 cu. m.) of screenings, containing from 60 to 70% of moisture, are removed daily. With a flow of 4 600 000 gal. per day (200 liters per sec.), the power consumed is 1.8 kw. per hour, but, for the two screens with auxiliaries, 14 h.p. is provided. With one screen in operation only one man is required, and the operating costs are small.

Drum Screens.

Quite different in design from the types mentioned heretofore is the "drum screen" (*Siebtrommel*) first used by Metzger, at Bromberg, and later improved and patented by Windschild, of Dresden-Cossebaude (Fig. 16). In the original form this screen consists of a short cylinder rotating on a horizontal axis, with the curved portion and a ring at the effluent end composed of perforated plates. The sewage enters at one end and passes out through the perforations, which intercept the grosser solids. The interior surface is divided, by radial plates, attached to the end plates, into from 16 to 20 compartments, in which the screenings are raised by the rotation of the drum. They are prevented from falling toward the center by a curved guide-plate concentric with the drum, until near the top, when they drop to a can, hopper, or conveyor, placed in the center. The material tending to clog the perforations is blown inward by an air jet delivered by a swinging nozzle on the exterior, which passes each hole at least twice during the rotation of the screen.

The usual dimensions are: diameter, from 8 to 13 ft.; depth, 1.6 ft.; width of annular end plate, 10 in.; aperture for the air jet, from 0.010 to 0.012 by 1.2 to 2.0 in. As to the perforations in the screen, Metzger found that with a wire mesh a fuzzy mat or film of detritus formed over the surface. He also found that holes 0.4 in. in diameter clogged more readily than smaller ones. Both water and steam were tried for cleaning, but were found objectionable by increasing the moisture in the screenings. Steam, too, resulted in an objectionable odor. Compressed air gave the best results, but, to prevent the dissemination of spray or mist throughout the room, the jet may be protected by a box-like covering.

Bromberg.—At Bromberg there are four sereens. Their diameter is 8.2 ft., and that of the perforations, 0.08 in. (Fig. 17). The screen rotates once in 50 sec., giving a rim velocity of 6¼ in. per sec. The



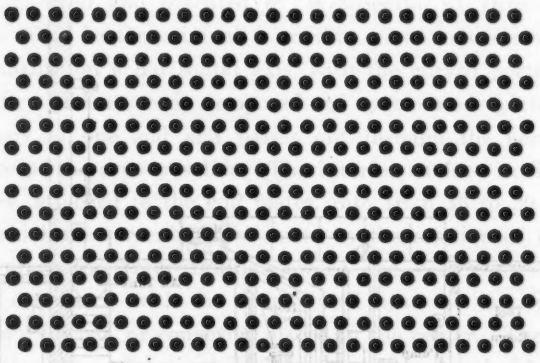
DRUM SCREEN AT TRIER

FIG. 18.

nozzle swings back and forth 85 times per min. With a slit 2 in. long, this requires 1 235 cu. ft. of free air, or from 70 to 77 cu. ft. of compressed air per hour. This has been considered too great, and the design is subject to improvement.

The screenings are removed by a band, 2 ft. wide. This machine screens 1 160 000 U. S. gal. per day, and 4¾ short tons (rising to a maximum of 10¾ tons) of material per million gallons are removed. This material contains from 40 to 60% of moisture. After drying on a warm plate to 34.3%, the weight is reduced to 7 short tons. Experiments lasting 8 days with two of these screens showed that the power required per screen was:

For turning the screen.....	0.9 kw. per hour.
For compressing air.....	0.3 " " "
Total	1.2 kw. per hour.



2–mm. PERFORATIONS FOR
DRUM SCREEN AT BROMBERG

FIG. 17.

The two screens averaged 1 195 620 gal. per day, and, on the last day, one screen cared for 64 192 gal. in 1 hour. Only one attendant was required during the operation. The cost for wages and power amounted to $2.45 per million gallons. If both screens were operated at a full capacity of 23 250 000 gal. per day, this cost would be reduced to $1.09 per million gallons.

The screen-house, with deep foundations, cost $15 600, and the mechanical plant, complete, $7 450.

One of the improvements introduced by Windschild was the use of a truncated cone, instead of a cylinder, for the drum, this form being better adapted to fluctuations of flow. During periods of least flow,

only the conical surface comes in contact with the current, and in wet weather, the sewage passes through both the cone and the annular end plate. Windschild also perfected the form and application of the air jet. A fair velocity of the perimeter of the screen is 4 in. (100 mm.) per sec. The air pressure necessary for cleaning varies from 0.5 to 2.0 atmospheres, but, ordinarily, 0.6 atmosphere is sufficient, increased to 0.8 or 1.0 atmosphere when the load is great. One nozzle requires 700 cu. ft. (20 cu. m.) of air per hour. In operation this may be cut off for considerable periods during times when the sewage is small in volume or weak. After operating 4½ hours without air, the screen was well cleaned in a few rotations by raising the pressure to 1½ atmospheres, and, even if a continuous film was allowed to accumulate over the surface of the screen, this could be removed by a pressure of 1.5 to 2.0 atmospheres.

Mainz Experiments.—Tests of a drum screen were made at Mainz in the winter and spring of 1910-11. The first two series were confined to the period from 8 A. M. to 5 P. M. It was claimed that the conditions were unfavorable, owing to the setting of the screen, which required the sewage to be pumped in order to avoid deep and costly temporary foundations, and that more or less solid material was broken up to such an extent by pumping that it passed through the screen. It was also claimed that the air pressure was kept unnecessarily high, resulting in excessive cost of operation.

The diameter of the screen was 11.5 ft. (3.5 m.) and that of the perforations 0.12 in. (3 mm.); the width of the conical band was 2.73 ft. (0.83 m.), and that of the annular plate at the end, 1.32 ft. (0.52 m.). The total screen area was 103 sq. ft. (9.6 sq. m.), 55% of which was free opening. The normal capacity was 1.75 to 2.8 cu. ft. per sec. (50 to 80 liters per sec.) with a submerged surface of from 13.4 to 14.5 sq. ft. (1.24 to 1.34 sq. m.). The air pressure at the nozzles was 2 atmospheres. The total power provided was a 5-h.p. motor. As one revolution required 110 sec., the velocity of the periphery was about 4 in. per sec.

The power required to operate the drum alone was, in the first experiment, 1.5 to 1.9 kw. per hour, and in the second, 2.0 kw. per hour. For running the compressor, 2.4 kw. per hour were consumed in the first experiment, compressing to 1 atmosphere, and 3.2 kw. per hour in the second, compressing to 1.5 atmospheres.

In the third experiment one-quarter of the drum was covered with brass plates having 0.04 by 0.08-in. (1 by 2-mm.) slots and three-quarters with copper wire with 0.04, 0.06, and 0.08-in. (1, 1½, and 2-mm.) mesh. These results were more favorable as to power required, but indicated the desirability of some alterations of design.

The results in detail are given in Table 5*.

In general, it may be said that, notwithstanding the unfavorable conditions mentioned, and with a sewage containing barely 1 ton of suspended matter per million gallons (0.109 kg. per cu. m.), the screen removed from 46 to 61% of the solids, or from 0.46 to 0.52 cu. yd. per million gallons. The screenings contained about 75% of moisture. The cost ranged from 89 cents to $3.42 per million gallons, decreasing with an increase of flow.

The superintendent of the plant reported the operation of the screen as cleanly and without spattering or objectionable spray or mist.

It was concluded from these tests:

1.—That, on account of the large percentage of free opening, the exposed surfaces are unusually small;

2.—That, in spite of the limited exposed area of the screen, 53.5% of the suspended matter was removed;

3.—That the screen never clogged;

4.—That it did not fail to operate when overburdened;

5.—That no slime or rust spots appeared on the surfaces;

6.—That the cost of power was high, but that this was due in part to unfavorable conditions, and that this drawback would usually be offset by the small cost of installation for a given capacity.

Trier.—A drum screen was installed at Trier (Figs. 15 and 18) in December, 1912, to take the place of tanks. The latter were found costly to operate on account of difficulty in disposing of the sludge. The sanction of the Government to make the change was obtained, with the proviso that particles more than 0.06 in. (3 mm.) in diameter be removed.

The population of Trier is about 40 000. The water supply is 32 gal. (120 liters) per capita, and the sewage flow amounts to 1 270-000 gal. (4 800 cu. m.) daily, half of which runs off in 9 hours, or

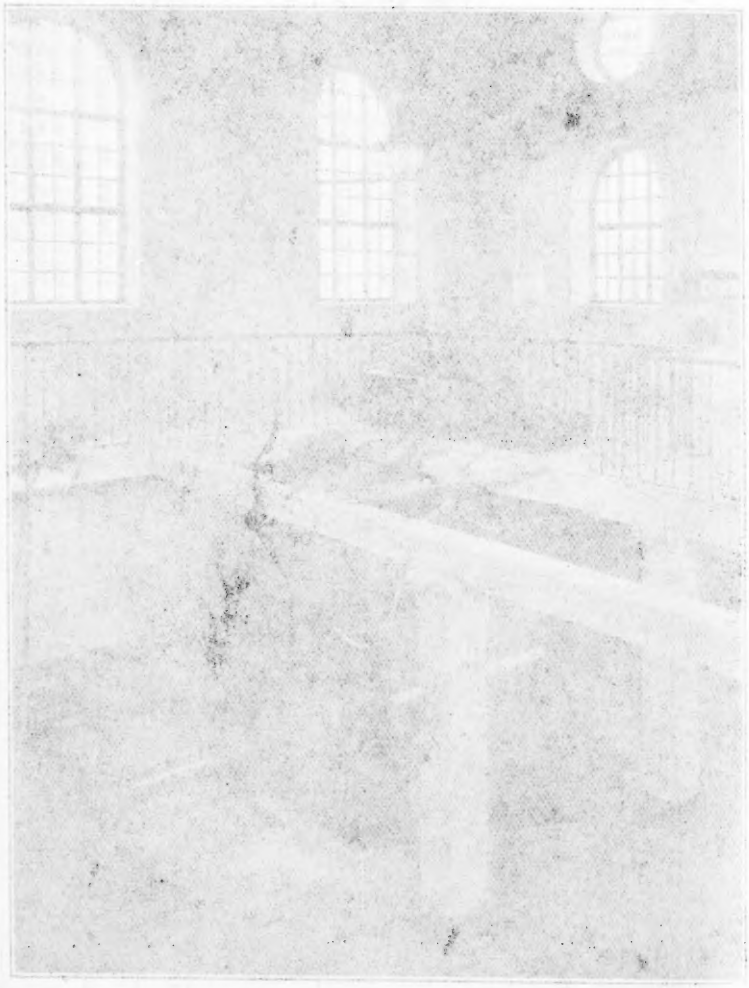
FIG. 18.—DRUM SCREEN AT TRIER. REAR VIEW.



at a rate of 2.6 cu. ft. (75 liters) per sec. The maximum rate of flow is 28 cu. ft. (800 liters) per sec., as determined by gaugings.

The diameter of the screen is 14.5 ft. (4.40 m.) and its width is 3.94 ft. (1.2 m.). The perforations are 0.10 in. (2½ mm.) in diameter and spaced so that only 0.04 in. (1 mm.) of metal remains between the holes. The screen plate is 0.05 in. (1.2 mm.) thick. The screen rotates once in 3 min.

There are sixteen radial plates which raise the coarser screenings and drop them into a central hopper. The fine material which remains on the screen is blown off by three swinging nozzles, the motion of which covers all portions that have been immersed. From the hopper the screenings are delivered to large perforated buckets from which, after draining, they are emptied.

The screen is operated by a 1-h.p. electric motor. A 2½-h.p. motor operates the compressor, ½ h.p. being required to swing the nozzle arms and an equal amount to circulate the cooling water in the compressor. The air is compressed to 2 atmospheres and delivered to a receiver, from which it is led to the nozzles by a pipe and hose.

The screen removes from 0.39 to 0.42 cu. yd. (300 to 400 liters) of material per day; 2.03 tons (3 650 kg.), or about 5.2 cu. yd. (4 cu. m.), have been removed in 11 hours. As this contains only from 50 to 60% of water, it is not sludgy in character, and can be handled easily. It is sold to market gardeners for 14½ cents per cu. yd.

The operation, according to Engineer T. Schürmann, has been found faultless, and no trouble has been experienced from spray or odor.

The total cost of the plant, including buildings, machinery, connections with the sewer, etc., was about $8 600 (36 000 Marks). The cost of operation, exclusive of interest and sinking fund charges, is given in Table 6.

TABLE 6.—Cost of Screening Plant at Trier.

Power, 4.32 kw-hr., 11 hr. for 365 days = 17 265 kw. @ 0.12½ Mark	=	2 158	Marks	= $513.60
One laborer @4.20 Marks per day	=	1 533	"	= 364.85
One helper @ 2.00 " " "	=	803	"	= 191.10
Lubricating oil, waste, and grease @ 0.40 Mark per day	=	146	"	= 34.75
Miscellaneous		60	"	= 14.80
Total cost		4 700	Marks	= $1 118.60
Deduct value of screenings sold		950	"	= 226.10
Net annual cost		3 750	Marks	= $892.50

The price paid by neighboring farmers for the screenings is 0.80 Mark per cu. m. = 15 cents per cu. yd. At 1 270 000 gal. per day,

the cost of operation, therefore, is $\frac{1\,118.60}{365 \times 1.27} = \$2.41$ per million gallons.

Drum screens have also been installed at Insterberg, Worms, Minden, Wartzen, and Osnabrück.

Osnabrück.—Osnabrück is a town of 83 000 inhabitants, 65 000 of whom are served by sewers. Only 17 000 are provided with water-closets. The normal volume of sewage is 1 600 000 gal. (6 000 cu. m.) per day, about 60% of which is collected by newly laid sewers, on the separate system, and pumped, the remainder being collected by combined sewers and delivered by gravity.

The screen is 16.4 ft. (5 m.), converging to 11.48 ft. (3.5 m.) in diameter, and 4.27 ft. (1.3 m.) deep. The perforations are 0.08 in. (2 mm.) in diameter. The maximum capacity of the screen is 33 cu. ft. (950 liters) per sec., with a temporary increase of water during storms, or the sewage from 90 000 persons.

The drum makes a revolution in from 2½ to 3 min. It is cleaned by two compressed air nozzles sweeping the conical portion and one sweeping the down-stream end, each swinging 75 times per min.

The power required for operation is about as follows:

For the screen	2.5 h.p.
For the compressor	5.0 "
For moving air jets	1.5 "
	9.0 h.p.

This is supplied by an alternating-current motor at 380 volts and 24 amperes.

Under ordinary conditions, the force consists of one man, but, during storms, an additional man is required.

The screenings amount to from 5¼ to 6½ cu. yd. (4 to 5 cu. m.) daily, or from 3¼ to 4 cu. yd. per million gallons of sewage, besides which, 0.65 cu. yd. (0.5 cu. m.) of grit is taken each day from a grit chamber placed behind the screen.

At the time the writer visited the plant, some of the perforations were stopped by wool fiber, but these were readily removed with a jet of water. Otherwise, the cleaning device appeared to operate perfectly, and the authorities are so well pleased that a second screen is to be installed soon.

The cost of the one screen, with grit elevator and motors, was

$3 570 (15 000 Marks), but the entire works, including two sewage pumps, air compressor, motor, a Diesel motor for emergency use, heating plant, an independent water supply, building, shower baths, etc., cost $59 500 (250 000 Marks).

The Weand Screen.—A modification of the drum type of screen is found in that invented by O. M. Weand, and now installed at Reading, Pa.,* Atlanta, Ga., Baltimore, Md., and Brockton, Mass. This screen (Fig. 19) consists of a cylindrical frame having a horizontal axis and covered with a fine wire mesh, which is protected by an outer coarse mesh of No. 12 wire. The sewage enters by and overflows from a channel at one end, and passes through the wire mesh to an outlet channel below. The material retained is worked to the farther end by the rotation of the screen, being carried forward by an interior spiral flange. At the farther end, it is lifted by short radial plates nearly to the top, and then falls to a chute delivering to a belt or trough.

Reading, Pa.—The Reading screen (Fig. 19) is 12 ft. long, 6 ft. in diameter, and is covered with Monel metal mesh having about 36 meshes per in. This fine mesh is protected by a $\frac{3}{8}$-in. screen of No. 12 copper wire. It is cleaned by $\frac{1}{16}$-in. water jets, 8 in. apart, from a pipe which swings back and forth longitudinally near the outer surface. Screened sewage instead of water was found to answer very well for this purpose, but crude sewage caused frequent stoppages. The screen rotates about 8 times per min.

The sewage flow amounts to 5 000 000 or 6 000 000 gal. per day, but the capacity of the screen was stated by Mr. Weand to be not less than 8 000 000 gal. per day.

Mr. Kuichling estimates the dried matter removed at 750 lb. per million gallons, or 90 parts per million out of 215 in the raw sewage, corresponding to an efficiency of 42 per cent.

The screenings amount to about 1 cu. yd. (20 to 35 cu. ft.) per million gallons, and have been analyzed as follows:†

Moisture	89.5 %
Mineral matter	2.8 "
Volatile "	7.7 "
	100.0 %

* The Reading screen is not now in use.

† "Sewage Sludge," by Elsner, Spillner, and Allen, p. 208.

They contain much paper pulp, and weigh from 65 to 70 lb. per cu. ft. After passing the screen they are transferred by a bucket elevator and worm conveyor to a tank and then drawn off to a centrifuge which reduces the moisture to 73 per cent. The cost of operation was stated by Mr. Weand to be about $1 per million gallons. Within the past year or so, the use of this screen has been discontinued.

Brockton, Mass.—At Brockton, the sewage is from a separate system, and amounts to 1 750 000 gal. per day, or 40 gal. per capita. It is stronger, therefore, than the average sewage of American cities. The screen is similar to that at Reading, but several mechanical details have been improved. No trouble has been experienced from clogging, except by grease, and, to remove this, the screen is stopped for ½ hour every night and washed with caustic soda. Weak points in the design appear to be lack of proper support for the fine mesh, corrosion of the interior spiral plate, and wear in the holes for the bolts securing the frames to which the mesh is attached.

Table 7 indicates the efficiency of the Brockton screen, the figures being averages for 1912.

TABLE 7.—EFFICIENCY OF BROCKTON SCREEN.

	Suspended Solids, in Parts per Million.		Percentage of reduction.
	Sewage.	Effluent.	
Total	983	282	71.3
Organic	897	245	72.7

During 1912, the average weight removed per day was 4 891 lb., or 1.4 tons per million gallons. In the first week of February of that year 4.5 tons, or 8 cu. yd. of screenings were removed from 2 000 000 gal. of sewage.

The screen required the attention of one man, three men being employed in 8-hour shifts.

Baltimore, Md.—Screens of the Weand type have been installed at Baltimore, Md. (Fig. 20), and Atlanta, Ga., primarily to prevent the clogging of the filter nozzles. The efficacy resulting from the Baltimore screen has already been referred to. At Atlanta the effluent

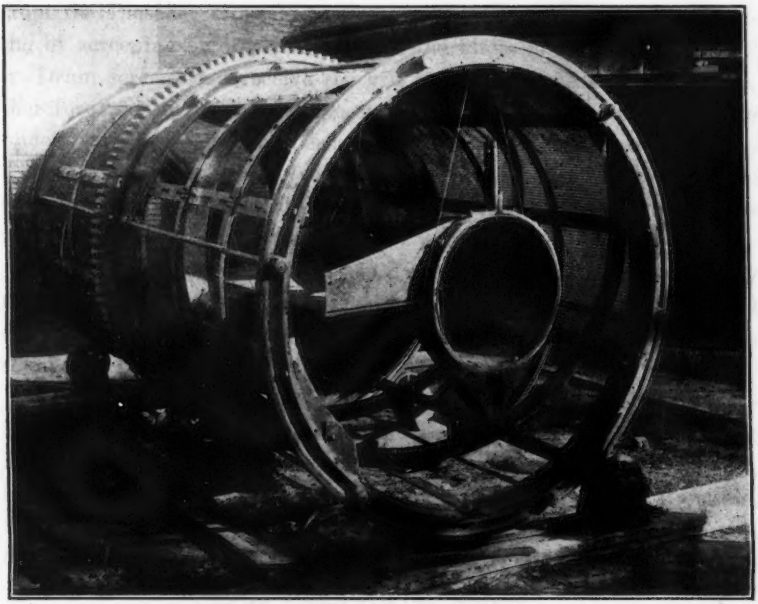


FIG. 19.—WEAND SCREEN PARTLY CONSTRUCTED. INLET END.

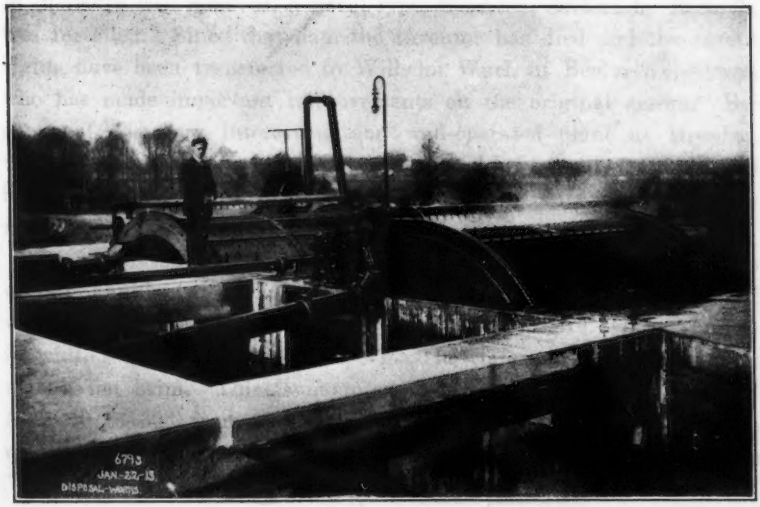

FIG. 20.—WEAND SCREENS IN OPERATION AT BALTIMORE, MD.

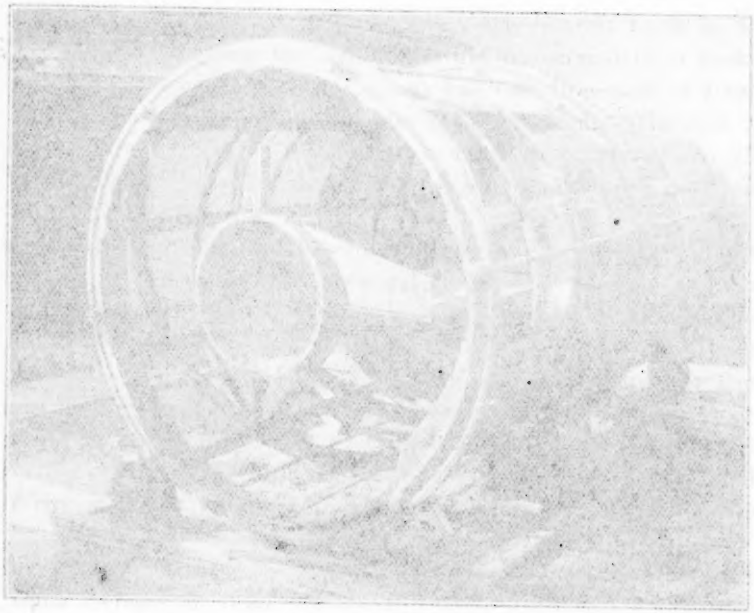


from the Emscher tanks has been so satisfactory that further cleaning by screening before application to the filters is not required.

Drum screens can receive the grit as well as true screenings, and, therefore, do away with the cost of grit chambers. They operate under varying loads at speeds that may be adjusted accordingly. They are compact, operate continuously, without hand labor, and the screenings, when cleaned by air, are delivered with a relatively low moisture content.

It is claimed for the Windschild screen, that there is practically no leakage past the outside of the drum, that losses from friction and deterioration are small, and that there is little backing up of the sewage by their use.

In the Weand screen, as installed at Reading and Brockton, there is a loss of several feet of head in the passage through the screen. Friction of the bearings originally gave much trouble at Baltimore, but this has been overcome by recent alterations. At Brockton, the interior flanges and the screen frames have shown considerable deterioration.

The Riensch-Wurl Screen.

Following the permission granted to the City of Dresden in 1903, to discharge sewage into the Elbe, if material greater than 3 mm. in diameter was removed, a novel type of screen, devised by Riensch, was installed. Since that date the inventor has died and the patent rights have been transferred to Wilhelm Wurl, of Berlin-Weissensee, who has made important improvements on the original design. Because of the very interesting and well-operated plant at Dresden, this screen has attracted much attention, and has already been adopted by a number of cities, including Bremen, Christiania, Stettin, Karlsruhe, Mainz, Strassburg, St. Petersburg, Toulon, and Astrachan.

In its present form the Riensch-Wurl screen (Fig. 21) consists of an annular disk surmounted by a truncated cone, both of which are perforated with slots from 0.04 to 0.20 in. (1 to 5 mm.) in width.* In general, the shape may be compared to that of a hat with a flat brim. This is mounted and rotates on a shaft inclined from 10 to 30° from the vertical, and is partly submerged. As a result, the floating solids are raised gently above the surface by the

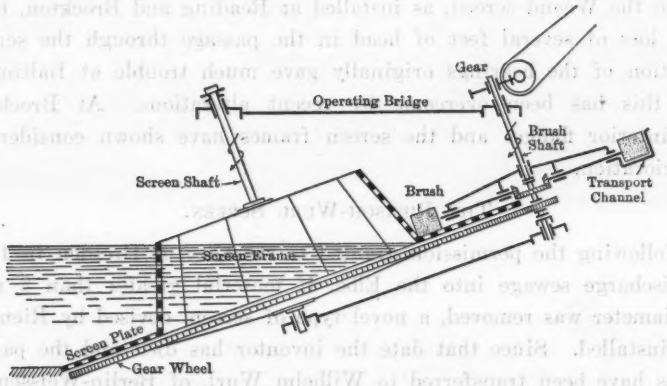
* It is claimed that ½-mm. slots are practicable.

rotation of the screen, and while in this position are brushed off to a container or a conveyor by brushes revolving on arms.

As the channel conforms to the rim of the disk, it is curved in section, and, therefore, there is a smaller variation in level for a given range of discharge than with a rectangular section.

Under ordinary conditions, the cone remains above the surface and so does not require the operation of the special brush provided to clean it, but, as the flow increases, this, too, is brought into service. The speed of rotation can be varied with the flow.

The screen plates are of brass or bronze. The perforations are beveled so that material which has once entered the slot will pass through without clogging.



ELEVATION OF A RIENSCH-WURL SCREEN

FIG. 21.

The brushes are of wild hogs' bristles or piassava fiber. They are cylindrical in form, and adjustable by counterweights so as to press but slightly on the screen. During operation, they rotate on their axes, so that the material is not pressed down or even scraped forward, but is rolled before the brushes until it falls on the conveyor or into the receptacle provided for it. By this means there appears to be no clogging of the holes except by a gradual deposit of grease, which is removed every few months by a jet of dry steam. The brushes themselves are cleaned by passing over a comb at each revolution. The speed and arrangement of brushes is such that each part of the screen is cleaned four or five times before being again submerged.

A "service bridge" is constructed across and above the screen, to which are attached the ball-bearings on which the screen frame is hung. There is only one bearing that is submerged, and this serves as a guide for the lower end of the shaft. It is protected by a stuffing-box lubricated by oil under pressure, and no trouble has been experienced as yet from the introduction of grit or other foreign material. The ball-bearings run in oil, but slow-moving parts are lubricated by grease.

One feature peculiar to the Riensch-Wurl screen is the large percentage of surface available for actual use.* The approximate area exposed to the sewage, the capacity and power required for screens of different sizes but with slots 2 mm. wide, are as given in Table 8.

TABLE 8.—SIZES, CAPACITIES, ETC., OF RIENSCH-WURL SCREENS.

Diameter, in feet.	Exposed area, in square feet.	Capacity, in gallons per day.	Horse-power required.
6	25	1 800 000	¼
12	90	4 200 000	
14	115	7 200 000	½
20	250	28 800 000	
26	405	103 000 000	2½

Screens of this type, with 2-mm. slots, will ordinarily remove from 30 to 40% of the suspended solids, and, with 1-mm. slots, sometimes from 50 to 60%, but the exact quantity depends on the character of the sewage. Under favorable conditions these percentages may be increased by one-half.

Ordinarily, the head lost in passing the screen is from ¾ in. to 4 in. (2 to 10 cm.), but this reaches 10 in. (25 cm.) or more during periods of high flow. It is estimated approximately as follows by Mr. Wurl: It is assumed that the effective opening is equal to about 25% of the submerged surface under any given rate of flow, and that from one-half to one-third of this is covered with screenings and, therefore, useless.

Let S = the submerged surface, in square feet;

A = the true effective area = say, $0.25 \times 0.4\ S$, surface = $0.1\ S$;

Q = the quantity of sewage, in cubic feet per second;

* Claimed by the manufacturer to be 80%, as compared with 33⅓% for band screens and 20% for wing screens.

$G = 32.2$;

C = a coefficient provisionally assumed as 0.4.

Then, the head lost, in feet, is:

$$H = \left(\frac{Q}{A\,C\,\sqrt{2\,G}}\right)^2 = \frac{Q^2}{10.3\,A^2} = 0.097\,\frac{Q^2}{A^2} = 9.7\,\frac{Q^2}{S^2}.$$

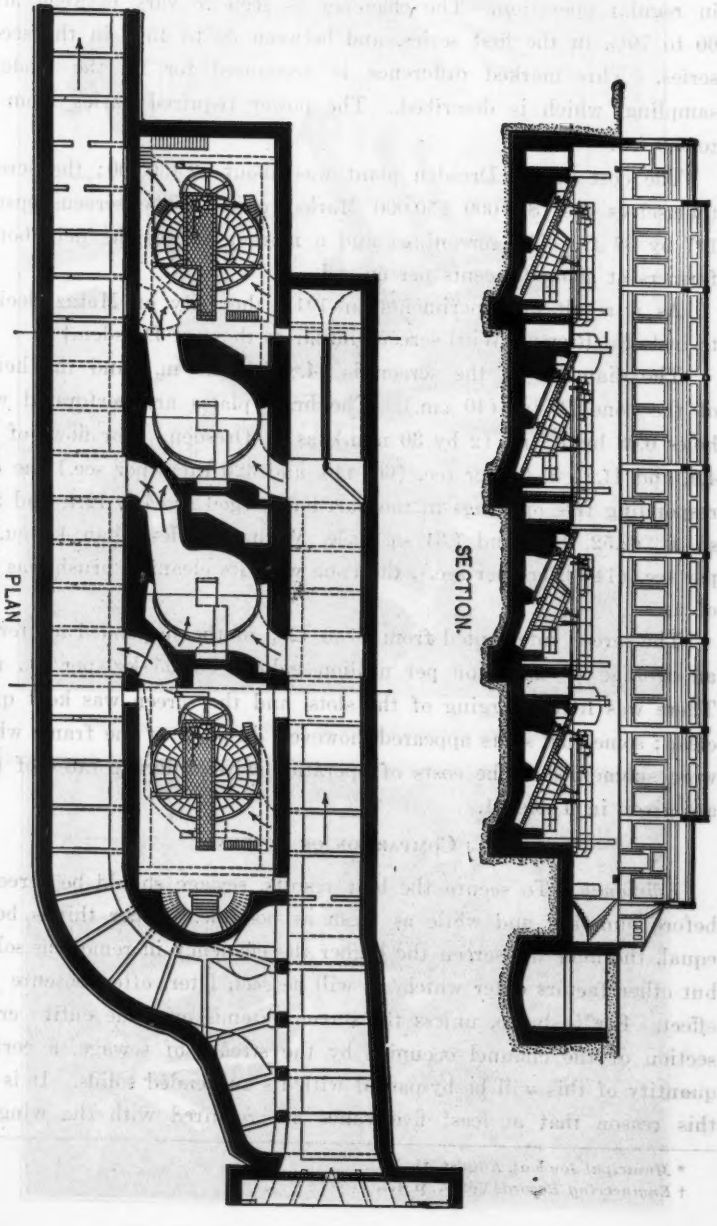
Dresden.—The Dresden plant (Figs. 22 and 23) consists of a grit chamber, a 2.65-in. (66-mm.) fixed-bar screen, and four Riensch-Wurl screens, the first of which was installed in 1910. The population served is about 530 000, but, of these, 280 000 had water-closet connections in 1913. The average sewage flow is 26 500 000 gal., including industrial wastes, or 50 gal. per capita daily, but this varies from 18 to 21 cu. ft. (500 to 600 liters) per sec. between 3 and 6 A. M. to about 70 cu. ft. (2 000 liters) per sec. between 11 A. M. and 5 P. M. This flow is easily taken care of by one screen, the other three being held in reserve for use in storms, when the flow increases at times to from 175 to 260 cu. ft. (5 000 to 7 500 liters) per sec.

Each of the screens (Fig. 24) is 26.2 ft. (8 m.) in diameter, of plate bronze 0.2 in. (5 mm.) thick, and contains 230 000 slots 0.08 by 1.20 in. (2 by 30 mm.) (Fig. 25). The total screening surface is about 600 sq. ft. (56 sq. m.). During ordinary conditions, the screen rotates once in about 3 min., but during storms this rate may be increased 50 per cent. About once in 3 or 4 months it is found necessary to clean the slots by steam. The head required to pass the screen varies from 2 to 12 in. (5 to 30 cm.). It averages about 4 in. (10 cm.), and often reaches 6 in. (15 cm.).

After passing the screens, the effluent is pumped with a lift of 23 ft. (7 m.) during high water, to the Elbe, where it is discharged by a 4-ft. (1.2-m.) pipe at a depth of about 6 ft.

An average of 25.6 cu. yd. (19.7 cu. m.) of screenings, or 0.97 cu. yd. per million gallons, or 0.09 cu. yd. per 1 000 inhabitants contributing, were removed daily in 1913, and contained 84% of moisture. This material is placed in a dump where it drains to about 75% moisture before removal by farmers, who pay 4½ cents per cu. yd. (0.25 mark per cu. m.) for it. The odors about the screening dump are quite offensive.

Tables 9 and 10, which are summaries for the two years beginning May 1st, 1912, and March 1st, 1913, give the results obtained



DRESDEN SCREENING PLANT

Fig. 22.

in regular operation. The efficiency is seen to vary between about 60 to 70% in the first series, and between 30 to 45% in the second series. This marked difference is accounted for by the mode of sampling, which is described. The power required varies from 2.5 to 3.0 kw.

The cost of the Dresden plant was about $2 150 000; the screens themselves cost $12 000 (50 000 Marks) each.* The screen-house is 197 by 37 ft. The screenings find a market among the neighboring farmers at about 9½ cents per cu. yd.

As a result of experiments in 1911, the City of Mainz decided to install a Riensch-Wurl screen similar to those at Dresden.†

The diameter of the screen is 14.8 ft. (4.5 m.) and the height of the cone 16 in. (40 cm.). The brass plates are perforated with holes 0.08 by 1.2 in. (2 by 30 mm.), as at Dresden. For flows of 2.1, 4.9, and 11.2 cu. ft. per sec. (60, 140, and 320 liters per sec.) the corresponding free openings in the part submerged are 7.2, 12.4, and 21.2 sq. ft. (2.52, 4.29, and 7.31 sq. m.). With rates less than 4.9 cu. ft. per sec. (140 liters per sec.), the cone with its cleaning brush was out of use.

The screen intercepted from 36 to 42% of the suspended matter, or an average of 0.395 ton per million gallons (0.095 kg. per cu. m.). There was little clogging of the slots, and the screen was kept quite clean; some rust spots appeared, however, on parts of the frame which were submerged. The costs of operation with different rates of flow are given in Table 11.

Comparison of Screens.

Efficiency.—To secure the best results, sewage should be screened before pumping and while as fresh as possible. Other things being equal, the finer the screen the higher the efficiency in removing solids, but other factors enter which, as will be seen later, often obscure this effect. For instance, unless the screen extends over the entire cross-section of the channel occupied by the stream of sewage, a certain quantity of this will be by-passed with its suspended solids. It is for this reason that at least five vanes are required with the wing or

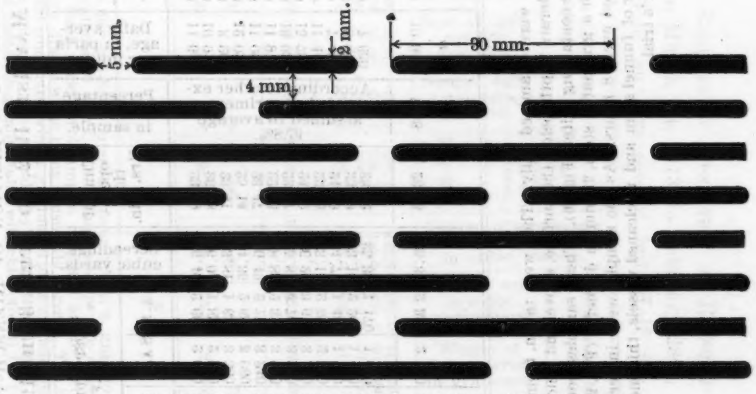
shovel-vane type of screen, and an invert depressed so that every portion of the stream will have to pass through one vane. To insure against leakage past the Riensch-Wurl screen, adjustable plates are set in the channel close to the periphery of the screen plate.

The efficiency also depends on whether the screening surface consists of bars, perforated plates, or a wire mesh, whether the solid particles are broken up by abrasion due to too high velocities or are macerated, so as to be carried through the screen by the current, or whether they are pressed through in the process of cleaning. Velocities through the screen should be moderate, and for this reason it is better that the motion of the screen should not be against the current, and that it should be adjustable.



SLOTS IN RIENSCH-WURL SCREEN AT DRESDEN

FIG. 25.

Round bars are probably undesirable, as they allow floating solids to enter and become wedged in the openings. Bars of a thin rectangular section are preferable as offering less resistance to the flow and having greater strength than other forms for the same quantity of metal. At Hamburg, the links are 0.20 in. (5 mm.) thick and are 0.6 in. (15 mm.) apart; at Frankfort and Elberfeld the bars are 0.12 in. (3 mm.) thick and are 0.4 in. (10 mm.) apart. Experiments made on wooden strips, 3 in. by ½ in. in section, at Cornell University* indicate a co-efficient of discharge of 0.811 if the sides are left parallel, increasing to 0.832 if sharpened on the down-stream edge, and becom-

FIG. 26.

Six samples were examined daily. They were taken, from 4 A. M. to midnight, from a moderate depth below the surface, above and below the movable screen, by buckets containing 1 liter (Fig. 26). These samples were decanted into a glass funnel with a graduated stem, 21 mm. in diameter (Fig. 27). The settled sludge was removed every 8 hours. As the samples were imperfect, because of the small diameter of funnel stem and uncleaned vessels, this method was abandoned after a year's trial.

Six samples were taken every fourth dry day at 4-hour intervals, from 2:30 A. M. until 10:30 P. M., at designated points above and below the screen by a "Hofer" apparatus (Fig. 28) containing 20 liters. The samples below the screen were taken on the average about 20 sec. later than those above, depending on the velocity. Each series of 6 samples collected at the two points was placed in a vessel holding 120 liters. From these vessels 10 samples of 1 liter each were drawn while being constantly stirred. The latter average daily samples from above and below the screen were poured into a tin funnel (Fig. 29) connected with a graduated glass cylinder 35 mm. in diameter and having a capacity of 150 cu. cm. All the sludge deposited within 4 hours was collected in the cylinder by jarring the funnel. It was then removed and the contents of the cylinder sent to the laboratory (after being rendered bacteriologically stable with chloroform) for further examination.

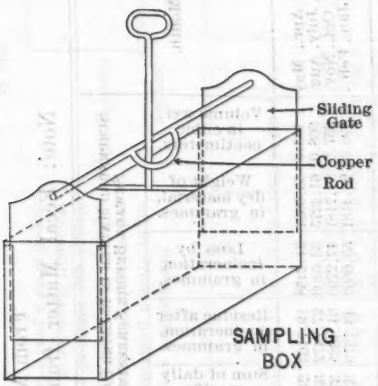

FIG. 28.

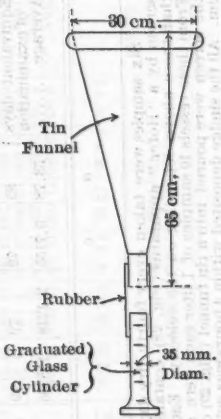

FIG. 29.

ing 1.032 if sharpened on both edges. The great advantage in the latter cannot be availed of, for the same reason that round bars are objectionable. In the shovel-vane screen at Gleiwitz, the curved bars taper on the down-stream side or toward the center of the screen. Aside from the small hydraulic advantage, this permits material once passing the up-stream surface of the vane to pass through freely.

TABLE 11.—COST OF OPERATION OF SCREENS AT MAINZ, WITH DIFFERENT RATES OF FLOW.

11.2	320	0.32½	0.036

Perforated plates, as in the Riensch-Wurl and Windschild screens, have an advantage in intercepting straws, matches, hair, and fiber which might pass between bars or even slots with equal spacing.

The American wire-mesh screens of Weand and Jennings are the finest of all, each mesh, including the wire, being only about 0.03 in. (0.75 mm.) square. Objection has been found with mesh screens in

that they promote the disintegration of the solids, so that an appreciable quantity passes through with the liquids. This was observed by Watson in connection with a Carshalton screen at Birmingham, and in connection with the Riensch-Wurl screen, and has also been mentioned with reference to tests of the shovel-vane screen at Gleiwitz.

A very important feature in any screening device is the method of cleaning, as the thoroughness of this operation directly affects, not only the efficiency, but also the cleanliness of the plant and the reliability of operation. There are many ways of cleaning bar screens. In some, particularly in England, the fixed bars are cleaned by movable rakes, but as it is preferable that all cleaning be done above water, in order to prevent the escape of broken-up particles with the effluent, it follows that the screen itself should raise the detritus to the proper elevation for removal. This is a feature of all the fine screens which have been described in detail herein.

The Hamburg screen is cleaned automatically by a hard-rubber rake or comb which engages the links after they have passed over the top, and is then withdrawn past a scraper which causes the screenings to fall on a belt conveyor. The motion of both rake and scraper is transmitted from a cam on the driving shaft by a system of levers. The device is carefully designed and appears to work satisfactorily.

The Jennings screen is cleaned by a jet of compressed air. Where grease collects in spite of this, it may be removed by the substitution of steam for a short period. The screenings are then removed by a conveyor. So far as known, this screen has not yet been tested out with domestic sewage.

Wing screens are generally cleaned automatically by a scraper which may, or may not, be followed by a brush. At Elberfeld it is found necessary to clean out the spaces by hand about once a week. This takes about ½ hour, but does not interrupt operation. At Bradford, England, where the sewage contains considerable wool fiber, the Engineer, Mr. Joseph Garfield, has found, after much experimentation, that this is most readily removed by a rake which operates on each vane when brought to and held in a horizontal position.

The shovel-vane and drum screens have an advantage in the removal of the screenings chiefly by gravity, the residue only being removed by a brush or jet.

With the Riensch-Wurl screen, the material is brushed off the smooth plates by automatically operated brushes. As already mentioned, it has been claimed that this operation forces some of the material through the slots, but to the writer the removal appeared to be very complete. Once in 3 or 4 months, however, sufficient grease is deposited in the slots to necessitate its removal by a jet of superheated steam.

Metzger experimented with various methods of cleaning perforated drum screens, and concluded that compressed air was most efficient and inoffensive. It has the advantage of blowing the detritus into the drum and delivering it with less moisture than, for instance, occurs in screenings from the Weand screen, where the mesh is cleaned by moving jets of water. Screenings from the Weand screen contain nearly 90% of moisture, but in those from the Windschild screen the quantity is only two-thirds as great. The reason for so much moisture in the Jennings screenings is not apparent. A further objection to cleaning by water jets is the disintegration of the solid material, allowing it to pass the screen.

The thoroughness of screening is best indicated by the parts per million of dried suspended matter removed from identical sewages. Some valuable data of this kind were contained in a paper by Emil Kuichling, M. Am. Soc. C. E., read before the New Jersey Sanitary Association in December, 1908, in which the material removed by grit chambers and screens is given in pounds of dry matter per million gallons of sewage, but such information is not often obtainable from the reported results of screening. If one cannot find the parts per million of suspended matter before and after screening, the next best information is the cubic yards (or tons) of screenings secured per 1 000 population, or per million gallons of sewage, and the percentage of contained moisture. A record of this, kept at every fine-screening plant, would not require great effort and would furnish most desirable information regarding the efficiency of the screen and of its operation. It should be borne in mind that the weight of wet screenings is materially reduced by a brief period of draining.

Table 12 contains general data of this nature for the several types of screens under consideration, which the writer has collected.

The results stated in Table 12 do not indicate the increased efficiency due to fineness of screen that one would naturally look for. More

good experiments with different types of screens, and under identical conditions, are needed, such as those attempted in the comparative tests of the Windschild and Riensch-Wurl screens at Mainz. In general, the data collected show that from ½ to 1½ cu. yd. or more of screenings may be removed from 1 000 000 gal. of ordinary domestic sewage at a cost of from $1 to $2, depending on the conditions. Further experience will probably develop the fact that care in operation has much to do with the station efficiency of any fine screen. A case has been brought to the writer's attention where a change of administration was the apparent cause of a decrease of 16% in the annual efficiency. The importance of using the most approved method of sampling has already been indicated with regard to the results obtained at Dresden.

It has been clearly demonstrated through experiments at Ithaca by Messrs. T. C. Schaetzle and E. R. Davis* with a ½-in. wire mesh screen, that the efficiency varies greatly with the strength of the sewage. At 4 A. M., 2.6 lb. of dry material were removed per million gallons, and at 11 A. M., 104 lb., with an average for the 24 hours of 52.7 lb.

To obtain true average efficiencies, the hourly efficiencies should be weighted according to the rate of flow, in a way similar to that by which composite samples of average water or sewage are prepared for analysis. This is a point, by the way, which appears to be generally neglected.

The influence of pumping and of length of travel, in comminuting the solids and increasing the colloidal matter, should be kept in mind as factors which may cause a marked lowering of efficiency.

The effect of preliminary cleansing by coarse screens or grit chambers should properly be considered in passing judgment on the relative merits of different methods of fine screening.

Adequacy and Reliability.—All the fine screens which have been described depend on continuous motive power for operation, and, having this, they appear to be quite dependable within the ranges of sewage level for which they are designed. In the case of the band screen, the surface may rise nearly to the belt conveyor, which is usually just below the top; with the wing, shovel-vane, and drum screen, it may rise to a point just below the axle, and, with the Riensch-Wurl screen, to the highest point reached by the base of the cone during a revolution. Larger proportions of band and Riensch-Wurl screens

therefore are submerged during periods of maximum flow and less head room is required. As the range of level with a Riensch-Wurl screen is limited by the diameter and inclination, this type is not well suited to small volumes of flow combined with wide variations in level. Where subject to these conditions, the band screen offers advantages, as it may be of any length without appreciably affecting other dimensions or costs.

Operation should be automatic, as far as possible. It is nearly so in all these screens, except when the speed is to be varied or the screen is to receive a special cleaning. With speeds that are too low, clogging and backing up of the sewage may result. The fine deposit of grease

be secured, in order to furnish a reliable comparison between the efficiencies of different

† Including coarse screening, settling, and subsequent screening.

that usually occurs on any screen will require special removal at times, and, with fine perforations or meshes, a mat of fine fiber or hair may gradually form over the surface; otherwise, the cleaning devices appear to be effective.

Reliability of operation depends, also, on the design and workmanship. The simpler the design the better, especially as this facilitates renewals and repairs. The wing screen and some forms of band screen are simpler perhaps than the others, but serious objections under this heading have been pretty well met in the design of the other types. In reference to this it may be stated that the Carshalton screen is usually operated by the hydraulic power of the sewage itself, and, there-

fore is not dependent on outside sources of motive power. The possibility of operation by hand in case of accident to machinery is a claim made for the wing screen, but might apply as well to the others, if of small size.

Nuisances.—If properly operated and kept clean, there need be no objectionable odors or other offensive conditions in the neighborhood of works using these screens. Inside the station there is usually the smell of fresh sewage, which is not strong nor likely to be carried far. With septic sewage, of course, there is more danger of foul odors. Any spattering or spraying of the sewage caused by high speeds or improper design, especially in the application of air, steam, or water jets, for cleaning, increases the odor.

Another and more probable cause for offense lies in the disposal of the screenings. From observation of a great many plants, the writer is convinced that screenings should either be incinerated, artificially dried, or promptly removed from the works. During warm weather, this should not be delayed more than 24 hours from the time of collection. Offensive conditions may be mitigated by composting with sweepings. This question of disposal is one of much importance, and also one which is frequently neglected.

Accessibility.—All parts of a screen should be accessible, for cleaning, repair, and renewal, with the least interruption to operation.

The Hamburg screen is hung on a shaft so that the lower end may be swung above the surface when required. The rotation of the wing, shovel-vane, and drum screens renders all moving parts accessible, and, with the exception of the bearing at the foot of the shaft, this is true of the Riensch-Wurl screen. It is understood that this objection is to be overcome by suspending the screen from a bearing above. In the case of the Frankfort screen, nearly all the moving parts can be replaced without interruption of the flow.

First Cost.—The cost of a screening plant depends, not only on the screen with its auxiliary machinery, but, to a great extent, on the location, foundations, and size of chamber. Simplicity of design, compactness, and the loss of head resulting from its use are all to be considered; in fact, the last may control the selection. As the cost depends on so many factors, the figures of gross cost, which are usually the only ones published, are of little value in designing new plants. Relative costs cannot be given for the several types, but approximate

cost figures for Riensch-Wurl screens in Germany, as given to the writer by Mr. Wilhelm Wurl at the factory at Weissensee, are stated in Table 13. They show that the price increases with the size and capacity, and that the cost per million gallons capacity decreases.

With the drum or shovel-vane screen, it is possible to do away with the cost of a grit chamber, as these screens can handle this material as well as the screenings. The wear of combined sewage with its contained grit on a fine-mesh screen would make the removal of grit before screening desirable where these conditions obtain.

26 ft. 4 in.	160	12 000	48.40

Cost of Operation.—The costs of operation depend primarily on the power consumed, supplies, and attendance; but they also depend on depreciation, repairs, and renewals. The materials used should be durable, and subject to the least possible corrosion. The Windschild drum screen involves the expense of compressed air, but this objection may be counterbalanced by the decreased moisture in the screenings. The Riensch-Wurl and shovel-vane screens involve the periodical renewal of brushes. The latter type is not simple in design, and for this reason might cost more for repairs, but is believed to be well made. The Hamburg screen is subject to the wear on many moving parts. The Weand screen has shown indications of deterioration from corrosion and wear. Experience with these screens has been too brief to assign to each a probable period of life. One can only form an opinion in each case from its design and the conditions under which it is to operate.

FINE-SCREENING VERSUS SEDIMENTATION.

It has been shown by the data already presented that in the matter of efficiency the best fine-screening will compare well with such tank

treatment as may usually be looked for. That is, from 30 to 50% of the suspended solids may be removed by fine screens, as compared with 50 to 65% by sedimentation.

Emscher tanks have a particular advantage in producing a sludge which is inoffensive, even if stored for a considerable period, and may be used for filling in waste land or, possibly, as a filler for fertilizer.*

Tank treatment uses up little head and is subject to little deterioration, such as is inevitable with machinery of any kind, and although the cost of attendance may be a little greater, such attendance, except for general supervision, may be of a somewhat lower grade than is necessary when motors, screens, conveyors, and possibly boilers, engines, or air compressors have to be looked after.

Monti, after the Berlin experiments already referred to, concluded: "that although this fine screening removes all of the offensive-looking matter, yet the liquid remains quite turbid, and that much better results can be obtained by a few hours' sedimentation in large tanks."†

This is confirmed by G. M. Wisner, M. Am. Soc. C. E., who concludes, from experiments at Chicago,‡ that "there is little or no improvement in the stability of the local sewage due to screening through a device with 40 meshes to the inch."

On the other hand, tank treatment requires considerable area, and this is sometimes difficult to secure at moderate cost. It would be a great expense, for instance, in some parts of New York City. Then, with plain sedimentation, a large volume of watery sludge, which becomes very offensive if stored, must be disposed of, and this means an additional area for drying, with, perhaps, additional cost for artificial drying or for transportation to sea while in a crude condition. Emscher tanks require less land than other forms, but are more costly to construct, their great advantage being the favorable quality of the sludge.

The following extracts from a report by George W. Fuller, M. Am. Soc. C. E., to the Metropolitan Sewerage Commission of New York,§ are of especial interest, as coming from one who can speak with authority on these matters. He says:

---

* "Fresh and Decomposed Sludge," L. C. Frank, *Engineering Record*, Vol. 68, p. 331.

† E. Kuichling, *Proceedings*, Thirty-second Annual Meeting, New Jersey Sanitary Assoc., 1908.

‡ "Sewage Disposal," by George W. Fuller, M. Am. Soc. C. E., p. 381.

§ Report of April 30th, 1914, pp. 209-210.

"Fine screens afford the cheapest way of removing visible objects of sewage origin from the waters receiving sewage where such screening treatment alone is sufficient for obtaining satisfactory results. Under conditions where the limit is at times reached in the amount of clarified sewage which a watercourse will oxidize satisfactorily, settling tanks as a general rule are cheaper to install than screens, because for a given cost they will remove a greater quantity of organic matter.

* * * * * * * *

"In my opinion, screens are preferable to settling tanks only where it is desirable or necessary to remove only relatively large sewage matters in suspension. Where settling solids would form deposits in the watercourses if screening alone were adopted, to install settling tanks will prove wiser than to install fine screens."

Screening plants, however, are very compact and, with grit chambers, need never occupy more than a fraction of a city block. The process is cleanly and largely automatic, requiring very little attendance. The product is much more readily handled, as it contains less moisture, as a rule, than sludge—from 75 to 85% instead of 90 per cent. It is true that some screenings may contain as much moisture as well-digested Emscher sludge, or perhaps more, but it is not, as in the latter case, in a liquid condition, but may be transported in ordinary wagons or cars after a brief period of draining.

If a recovery of grease or fertilizing value is considered, the dried screenings will be found, as a rule, to contain much more organic matter than the dried sludge, and, therefore, pound for pound, to yield a greater return. Unless the plant is of considerable size, the screenings can best be drained and then burned under boilers or in a special incinerator, plans for which, it is understood, are now under consideration by a suburb of New York City.

To sum up, although screens may remove less material than tanks, the difference is not very great in the best types of each, and still less when one considers the organic constituents, the presence of which is most objectionable in an effluent. The land required is much less than that required for tanks, and the cost of installation is probably less, although this depends on local conditions. As to gross annual charges, no general comparison is possible, but it is believed that screens will often be found quite as economical as tanks if the fixed charges are included and the total dried organic matter removed is used as a basis of estimate, in spite of the fact

that there is greater deterioration and that higher rates of wages may be required with screening.

The head lost in either case need not be great, except in the original design of the Weand screen, or where, as with the Carshalton screen, it is used to develop power for operation.

Conclusion.

The points which the writer has attempted to bring out may be summarized as follows:

The use of fine screens for sewage deserves more serious consideration than it has received heretofore in America. Although tank treatment will continue to be the standard preliminary process, under most conditions, from economic considerations, there are now several screens which will remove approximately as much of the organic suspended matter from sewage while occupying much less space and delivering a product that is both richer in manurial ingredients and more readily handled than tank sludge.

For the foregoing reasons, it is the writer's opinion that fine-screening will be adopted in the future by many towns situated on bodies of water which are capable of assimilating the effluent; possibly, also, as a preliminary process to tank treatment, filtration, and disinfection. On the other hand, the relatively high cost of attendance and the probable lack of a market for the screenings, when compared with conditions abroad, will probably serve to prevent the marked increase in their use in the United States which has been experienced in Germany.

In view of a reasonable development of fine-screening in America, more fundamental data as to efficiencies and costs are greatly to be desired. These are rarely available in their best form, even in Germany.

The volume of sewage received at the plant, or the population served, should be recorded, and also either (*a*) the suspended solids and total organic matter, or (*b*) the parts per million of average suspended solids in the crude sewage, the weight of the dried grit and screenings, and the percentage of each which is organic.

a.—The suspended solids and total organic matter in the crude sewage and after each operation should be recorded for the different times of the day and week, and then, if weighted according to the

flow when sampled, it will furnish the quantity of these essential materials that have been removed by the screens and such preliminary devices as coarse screens and grit chambers.

b.—A record should be kept of the parts per million of average suspended solids in the crude sewage, the weight of the dried grit and screenings, and the percentage of each which is organic.

Data of this kind from different sources would then be comparable and of much value in planning new works. The costs, too, not only of the screens, but of foundations, auxiliary machinery, and housing, with those for supplies and attendance, should be matters of record. So much stress laid on these things would perhaps be unnecessary, but for the fact that such essential data are, with few exceptions, not to be had.

Finally, the adoption of screens should be considered:

1. Where the principal requirement is the removal of the larger solid matters;
2. Where land values are high;
3. Where the cost of excavation for tanks is high;
4. Where the cost of sludge disposal is high, or where it is likely to cause objectionable odors; and
5. Where the recovery of grease and fertilizer is an important factor.

With openings not more than 0.10 in. (2½ mm.) in size, fine-screening should remove at least 30% of the suspended solids and 20% of the suspended organic solids from ordinary domestic sewage, or 0.1 cu. yd. of screenings, containing 75% of water, per 1 000 population daily.

The writer expresses his sincere desire that the many members of this Society who have studied the subject of fine-screening, will present such information and as many suggestions relative to the matter as possible.

STORAGE TO BE PROVIDED IN IMPOUNDING RESERVOIRS FOR MUNICIPAL WATER SUPPLY.

Discussion.*

BY MESSRS. H. T. CORY AND ALLEN HAZEN.†

Mr. Cory.

H. T. CORY, M. AM. SOC. C. E. (by letter).—Occasionally in life, one "comes to scoff and remains to pray." That, metaphorically speaking, is the writer's experience with Mr. Hazen's paper. In general, water storage required depends primarily on the run-off (including quantity and distribution throughout the year), and its estimation is a very dangerous and complex proceeding. The writer has seen such disastrous results from attempts to apply run-off data and run-off relationships from precipitation obtained in one section of the country to a locality or stream in another section, often near-by, that Mr. Hazen's paper was taken up in a spirit of impatience. So many tragic wrecks are strewn throughout the Far West from this sort of thing, that it is difficult to be tolerant of the elaborate methods constantly being suggested by ingenious mathematically inclined engineers for "deducing" discharges of ungauged streams. The instances cited by Mr. Taylor‡ are very pertinent, and the writer knows that the particular cases he mentions are presented fairly in his discussion.

It was largely a matter of luck, therefore, that the writer was led to glance over Mr. Hazen's paper in sufficient detail, before throwing it aside, to discover that it was not another and probably the most serious proposal yet made to apply mathematical methods to insufficient data in an endeavor to use observed run-off data covering a short period

* Continued from May, 1914, *Proceedings*.
† Author's closure.
‡ *Proceedings*, Am. Soc. C. E., January, 1914.

Mr. Cory.

of time, with a view to "expanding" them into records of sufficient length apparently to justify the design of hydro-electric engineering works to the third decimal place.

The paper, as a matter of fact, is of a totally different character. It was read with very great interest and profit—also with very considerable difficulty, in spite of the fact that the writer, as a student, was given the method of least squares more fully than is usual in American technical institutions, and, in addition, taught it and its applications in engineering work to his students for several years while in charge of engineering departments in two of the larger American universities. It is probable that most members of the Society found it still more difficult to follow the argument.

These two things are probably responsible for the little comment really pertinent to the paper itself which has been brought out. This small amount of discussion is greatly to be regretted, because the contribution, as a matter of fact, is most noteworthy, in several ways. The method of examining hydrographic data itself is of striking importance and interest, as well as the application of graphical methods to the theory of probability, or method of least squares, as it is more usually called.

The title and the context show that the author considers only storage for municipal supplies, and limits his conclusions to regions where hydrographic conditions are similar to those obtaining in the North Atlantic States. The method of analysis, however, is a general one, and the writer will consider its application to general hydraulic work in the Far West, where irrigation and power development overshadow municipal uses. From such a standpoint, some statements and methods of treatment, although quite justified in the paper as presented, require some modifications. The discussion which follows has to do very largely with such features, and, as a whole, is from that standpoint exclusively.

It is unfortunate that the first paragraphs of the paper were presented in just the form they were, because, at the very outset, they give the reader—at least they gave the writer—an erroneous conception of its scope.

"There is undoubtedly a definite relation between the storage provided in an impounding reservoir on any stream and the quantity of water which can be supplied continuously by it. The relation, however, is a complex one, and our knowledge of its character is limited. The following study is made to see how far it may be possible to separate this complex relation into parts, some of them being of such a nature that they may be studied separately with definite results, and afterward to treat all the remaining variations on the basis of probabilities, using all data from a number of different streams; and to study them in comparison with the normal law of error.

Mr. Cory.

"Among the elements that can be studied separately are the following:

"1. The size of the catchment area.

"2. The mean annual run-off per square mile.

"3. The portion of water area and the loss by evaporation from it. This relation is a complex one, and data for determining it are less adequate than could be desired. Nevertheless, some approximations can be reached.

"4. The natural storage in lakes, or in deposits of sand and gravel and other pervious materials. Only approximate results for natural storage can be reached, but as these are found to have a great influence on the required storage, especially at relatively low rates of draft, they must be considered.

"5. Regularity in flow. Some streams have comparatively regular flows; in others the variation is much greater. This difference in regularity of flow can be taken into account by finding a coefficient determined from the record of each stream, and bringing this into the statement in such a way that variations from the normal are stated in terms of the 'standard variation'. In this way, records of streams having more regular flows and those having less regular flows may be compared with reference to other matters.

"For the present, all remaining elements of variations of flow of every description will be thrown into one group and studied in connection with the normal law of error."

As a matter of fact, not "all remaining elements of variations of flow of every description" are studied in connection with the normal law of error, but, instead, all the essential elements of flow. As stated under the head, "Data Used," on page 1946:*

"The first step is to reduce existing data to the land-area basis, and make a tabular statement showing the average flow per square mile for each catchment area * * *."

That is to say, start with the actually observed run-off reduced to a uniform basis for comparative purposes, which, in itself, is involved and is the result of all five elements specified in the second paragraph, and a great many more. Indeed, with the actually observed run-off once known for any considerable period, the size of the catchment area is ordinarily a matter of indifference; the mean annual run-off per square mile, or otherwise stated, is one summation of many which can be utilized; and the regularity of the flow can at once be observed, or computed in terms of standard variation, or otherwise. The proportion of the drainage area which is water surface, the loss by evaporation from it, and the natural storage in lakes or deposits of sand and gravel, are important, but only primarily as affecting corrections of observed run-off data from several streams, in order to put them on a comparative basis.

The essential thing, then, is that the entire paper (and the method of analysis which it presents) concerns the study of run-off data reduced to a common basis—regardless of how such data may have

* *Proceedings*, Am. Soc. C. E., November, 1918.

Mr. Cory.

been collected—with the view of estimating what may be expected from dryer years or years when excessively low flow will occur. Although it is undoubtedly true that the same method could be used for examining precipitation data, and, on page 1976*, the author points out that dry years may be classified, with reference to the quantity of rainfall, the quantity of run-off, or the quantities of storage required to maintain certain drafts, nevertheless, as far as the author's presentation as a whole is concerned, actual adjusted run-off is the only thing taken into account and analyzed.

It is thus seen that the third paragraph of the paper as such is misleading, and may give quite a wrong conception of its subject-matter and add considerably to the difficulty of following the line of thought.

As the author states, the first requisite for a successful study of probabilities in run-off and in storage capacities from run-off data, is a sufficient number of facts. To obtain these, the method actually used is to combine the records of several streams reduced to a comparable common basis, thus forming a single series covering a great number of years. The objection to such a method is obvious, but, as a matter of fact, not so great as would seem at first thought. In the light of present knowledge, the combination of records of streams from distant areas having widely different conditions is not justifiable, and a series made up from a number of streams in a relatively small area reflects no changes in climatic conditions which might take place in a long term of years. Mr. Marsh† points out that the average daily run-off from the Croton water-shed in the 18 years, 1869-86, was 346 000 000 gal., and in the 18 years, 1887-1904, it was 449 000 000 gal. This difference is 30% of the smaller, and 23% of the larger, figure. As a matter of fact, however, in the treatment proposed in the paper, the safe draft and the storage unit are expressed in terms of the coefficient of variation, which latter does not vary materially for the two periods. If the draft is taken in this way, the variation in the mean annual run-off does not enter into the problem in so marked a manner. The actual draft in any absolute quantity units obviously does, however, and, in applying the results of the analyses explained by Mr. Hazen, one must be careful to realize that if the figure taken for the mean annual flow is not the correct one, the quantity figures will be also in error, the extent of the error when above the critical storage point being, according to the author, about 80% of that in the mean annual run-off (page 2015*).

The limitation of the method in this direction, however, does not take away its value for analyzing data of the character under consideration. Obviously, no method of examining data is conceivable which would promise quantity results any more dependable than the figures

* *Proceedings*, Am. Soc. C. E., November, 1913.

† *Proceedings*, Am. Soc. C. E., February, 1914.

Mr. Cory.

for mean annual run-off from water-sheds. Serious errors in mean annual discharge are much less, and can be more easily avoided in a dependable manner, than almost any other kind of errors in hydrographic records. It is undoubtedly true that the relation between the run-off in any one year and the rainfall of that year is impossible to establish within reasonable limits, because of the tremendously complex character of such relationship. The relation between mean annual rainfall over two long periods of time and the mean annual run-off for the same long periods of time, in the case of any given water-shed, however, is a very different matter. The writer does not know just what the facts in this particular are in Eastern, Northeastern, and Southeastern streams, but, in California, where wet and dry cycles run from 8 to 10 years in length, there is no difficulty in judging very clearly from long precipitation records whether or not such low-year run-off and high-year run-off cycles exist. It follows, therefore, that the author's conclusion that his method of studying such an artificial series seems to be the best means now available for finding approximately some of the relations between flows and storage, is absolutely justifiable.

On page 1946*, it is stated under the heading, "Land Area Only as Basis", that the "published figures are revised by dividing the run-off per square mile from the total area, by one less the proportion of water area." This may be an empirical rule found to be correct for the territory which Mr. Hazen was considering, but otherwise the reason for so doing is not clear. Mr. Marsh's comments on taking equivalent land area rather than gross area seem to be pertinent. On page 1950*, it is said that storage is most conveniently stated in days' supply of a maintainable yield. This is evidently true as regards storage for municipal purposes, but it is not true for irrigation and power storage.

It is probable that a great many members began to "read rapidly" —and not understandingly—at the heading, "Probability Paper." The author states that this is:

"* * * paper ruled with lines spaced in accordance with a probability curve, or, as it is otherwise called, the normal law of error. The spacing of the lines for this paper was computed from figures taken from probability curve tables, and arranged so that the line which represents the summation of the probability curve, when plotted on it, is straight."

This is a very short and interesting, but not satisfactory, description. As far as the writer is aware, this is the first time, in engineering literature at least, where probability paper has ever been used, its use suggested, or its preparation even touched on. The short description thus given is, to say the least, not comprehensive, and, indeed, some "arrangement" of the figures taken from probability curve tables must be made in order to obtain the probability paper as given. Just what that arrangement is, the writer has not had time to figure out, and he can well understand that most engineers are

*Proceedings, Am. Soc. C. E., November, 1913.

Mr. Cory. not willing to use a new mathematical or graphical tool without at least understanding how it is prepared. The equation of a straight line when plotted on such paper would be interesting. It is obvious that in going into an entirely new field, as the author has in this paper, great conciseness is necessary in order to keep the contribution within reasonable length, but it is hoped that the discussion will bring out a little more information and detail regarding this new probability paper.

The definition of dry years is an excellent idea, and it is well to emphasize the fact that any given percentage dry year must be considered as a type, and not any one actual year.

On page 1978*, the author says:

"The importance of making the correction for daily results, when monthly records are used for the basis of calculation, will be realized when it is stated that in most cases this correction amounts to more than the allowance for evaporation."

Although this is practically true of the Eastern reservoirs discussed by the author, it is very far from being true in irrigation practice west of the Rocky Mountains. Indeed, in California, the evaporation loss from municipal reservoirs often amounts to more than 25%—being so great sometimes that the hardness of the water at the end of dry cycles is more than doubled. The same applies to the second paragraph on page 2007*, in which it is stated that the correction for the quantity of storage in the Croton water-shed, estimated by Mr. Freeman some years ago, deduced by the method of analysis given in the paper, is 30%, "* * * an addition so large that it overshadows all allowances for evaporation, ground-water storage, and other secondary conditions * * *".

For Eastern conditions, where the annual precipitation directly on water areas is approximately equal to the annual evaporation therefrom, the author's methods of handling evaporation, as given on page 2032*, is doubtless satisfactory. However, where the evaporation is such a very important factor as it is in the Far West, it is absolutely necessary, in order to avoid very serious mistakes, to eliminate this item on both sides of all equations, and regard it as a part of the total draft, that is, the maintainable draft should be considered as the gross draft, and the net draft should be determined from it and the evaporation, using very short intervals of time and actual water areas for each of the respective time intervals. This is particularly true in the case of irrigation reservoirs, where the draft is not regular throughout the entire year but is concentrated throughout half the year or less, with a maximum daily draft frequently twice that of the average even for the short irrigation season.

As this is the case, in order to make the method general, it seems to the writer that regarding evaporation as one part of the total draft,

* *Proceedings*, Am. Soc. C. E., November, 1913.

just as the net draft is the other part, instead of using the method which the author suggests, is absolutely essential. Mr. Cory.

On page 2000*, the paragraph: "It is probable that 2 or more of the 5 years would follow consecutively in one period of several years of low average flow", might be misleading, because the method takes into account this very probability of a succession of dry years.

The paper would be a little clearer and more easily read were parenthetical descriptions of the kind of paper in the various figures indicated, arithmetic-arithmetic, arithmetic-logarithmetic, arithmetic-probability, and logarithmic-logarithmic papers being used without stating which is which.

On page 1996*, the author states that in the Eastern streams investigated, the annual flow will fall to 55% or less of the normal, once in 100 years. On the other hand, in Western streams it frequently falls to zero for 2 or 3 consecutive years in the case of some important streams. Indeed, the coefficient of variation of the Sweetwater River at the Sweetwater Dam is considerably greater than unity, being 1.38.

On page 1997*, the author states:

"It is obvious that the storage required to balance annual fluctuations in flow will increase with the coefficient of variation for the mean annual flows. It is not unlikely that the coefficient of variation may be used as a basis for measuring the storage in such a way that the results will be general, and will apply equally to all the streams within the range covered by this study."

With the view of ascertaining what results would be obtained by applying the method to some of the most variable of the Western streams, the writer examined the run-off data shown in Fig. 38—probably the most variable of any streams in the United States—and that of another series totaling 142 years from another locality (details not given) to see whether the coefficient of variation might be used as a basis for measuring storage. The results were startling, and are given graphically in Fig. 39. Unless it is a case of mere coincidence, which seems improbable, it appears that, not only the method, but this latter curve, can be appled to all streams within the range covered by the writer's study, as well as to all those within that covered by the author.

This is most significant. It indicates that the author has proposed a method by which is obtained a wonderfully effective tool for the use of hydraulic engineers—the figure showing storage units for various values of k for 80, 90, 95, 98, and 99% dry years, and is Fig. 30 extended as low as $k = 0.1$, through the examinations which the writer has just mentioned as having made. In this curve, the storage units equal the standard variation or the coefficient of variation multiplied by the mean flow, and k is the coefficient in the expression:

"Draft $= (1 - k \times$ Coef. of variation$)$ = Portion of mean flow used."

* *Proceedings*, Am. Soc. C. E., November, 1913.

Mr. Cory.

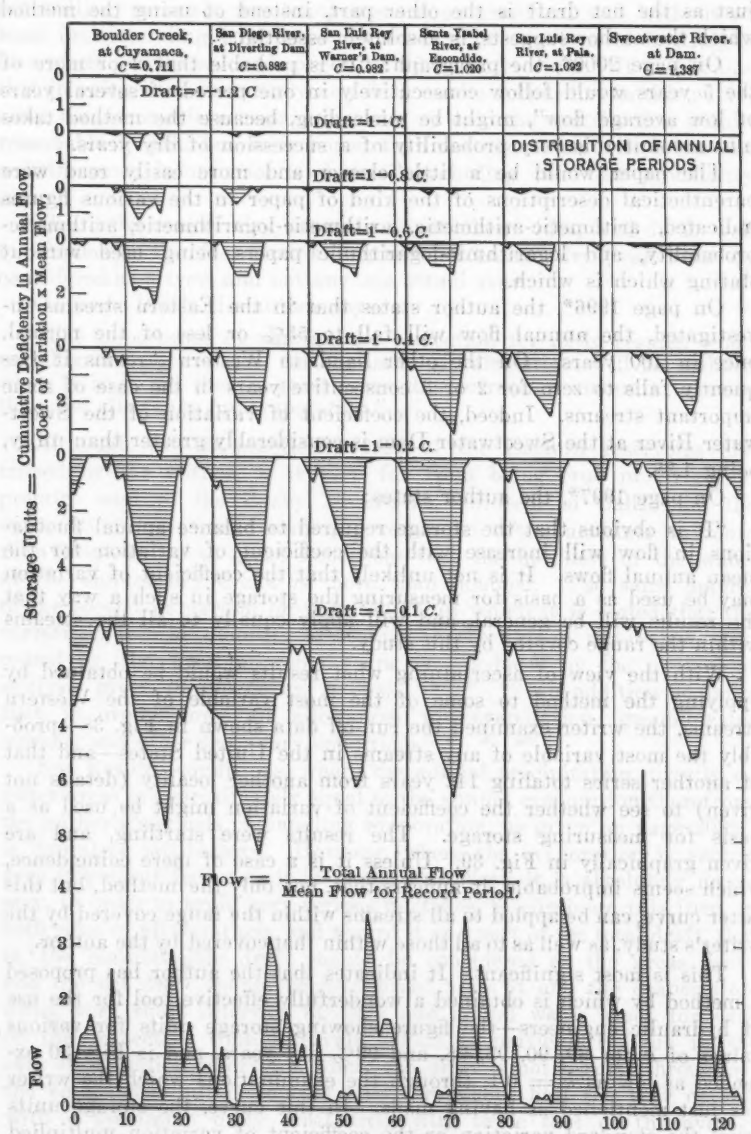

FIG. 38.

Mr. Cory.

It seems premature to suggest that this curve will hold true for streams or sets of streams in general localities, widely separated, and having excessive differences in run-off characteristics. At the same time, the curves do represent very closely the results obtained by the author in the streams which he examined in the New England and neighboring States, and equally well the data from some streams in the very southeastern corner of California and from some in its central portion. In the latter region, the run-off characteristics are quite as different from those in the southern end of California as they are from those selected by the author from New England territory.

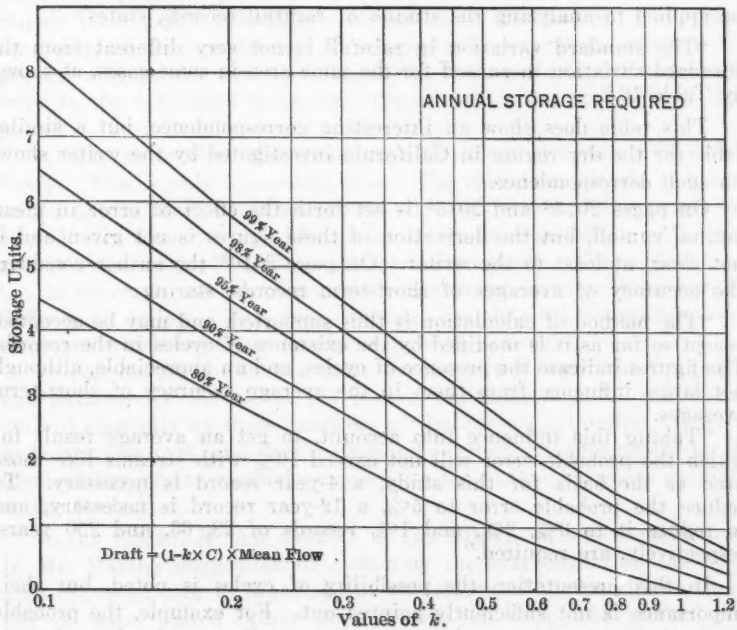

FIG. 39.

Should further investigation show that these curves are really general in their application and that their coincidence in the case of these exceedingly different sets of streams is not a mere matter of chance, the ability to determine very quickly the available draft from any stream with a given quantity of storage, or *vice versa*, by a half day's study of its yearly run-off data, will prove of almost incalculable value to the Profession. It is for this reason and for the desirability of determining quickly the limitations of the method and the propriety of its general application, that the small amount

Mr. Cory. of discussion which the paper has brought out is especially to be regretted.

It is important to remember that to the quantity of storage, as given by the curves in Fig. 39, must be added the actual monthly storage (corrected for daily storage) required to tide over dry seasons in the year, the estimation of which is considered in that part of the paper preceding page 1996*. Such monthly storage appears to be about 245 days for the complete development of the Eastern streams investigated by the author, and about 320 days in the California streams investigated by the writer.

On page 2009*, the author, having explained that the method can be applied to analyzing the studies of rainfall records, states:

"The standard variation in rainfall is not very different from the standard variation in run-off for the same area in some cases, as shown by Table 16."

This table does show an interesting correspondence, but a similar table for the dry region in California investigated by the writer shows no such correspondence.

On pages 2014* and 2015* is set forth the effect of error in mean annual run-off, but the derivation of these figures is not given and is not clear, at least to the writer. On page 2016* the author considers the accuracy of averages of short-term records, stating:

"The method of calculation is thus supported, and may be accepted, except so far as it is modified by the existence of cycles in the records. The figures indicate the presence of cycles, and an appreciable, although not large, influence from them in the average accuracy of short-term averages.

"Taking this influence into account, to get an average result for which the probable error will not exceed 10% with streams like those used as the basis for this study, a 4-year record is necessary. To reduce the probable error to 5%, a 12-year record is necessary, and to reduce it to 3%, 2%, and 1%, records of 28, 63, and 250 years, respectively, are required."

In this presentation the possibility of cycles is noted, but their importance is not sufficiently pointed out. For example, the probable error of the 18-year record, 1887-1904, according to the foregoing, is less than 5%, yet, according to Mr. Marsh's statement in his discussion, this average on the Croton water-shed was 23% greater than the 18-year period, 1867-86. Of course, the variation from the total mean is much smaller, but the safe dependable yield throughout the earlier period of 18 years is obviously the thing, and practically the only thing, of interest to hydraulic engineers in estimating dependable yield, particularly for municipal purposes. With regard to this point, it seems to the writer, as was expressed early in this discussion, that there was no use in hoping to obtain results by analyses of run-off records any more reliable than the figure for the mean annual run-off

* *Proceedings*, Am. Soc. C. E., November, 1913.

itself, and that the possibility of such dry cycles must be examined by a critical analysis of the precipitation records over the same general region, which ordinarily extend back very many times as long as run-off observations. Mr. Cory.

On page 2020*, in the equation for the probable error in the calculated maintainable yield of an Eastern stream above the critical point,

$$\text{Probable error} = \frac{0.55 \times \text{coefficient of variation}}{\sqrt{\text{number of years in record}}},$$

the reason for the use of the figure 0.55 is not clear to the writer. Also, the author's discussion: "Actual Probability of Shortage in Supply", on pages 2038-2040*, is not clear, particularly the reason for using 0.8 as a multiplier of the probable percentage error in the general average for the whole series, in order to obtain the probable error in the calculated mean flow, the storage being above the critical point.

It may seem that the writer has criticized the paper somewhat freely. This is only apparently true. The criticisms are all of a very minor nature, and would not be at all worth while if the paper was of ordinary importance. The presentation is remarkably well done, and is a fine example of clearness and conciseness. The subject matter, however, is not simple, and the argument is more than usually difficult to follow. For these reasons, the detailed suggestions and comment which have been made seem to be desirable.

In conclusion, the writer again expresses the hope that the paper, and particularly the use of the revised curves in Fig. 39, will be examined critically by those members of the Society interested chiefly in hydrographic work, and that their results and experiences regarding the applicability of the method proposed by the author be given promptly to the Society.

ALLEN HAZEN, M. AM. SOC. C. E. (by letter).—There is much force in Mr. Marsh's suggestion of reckoning the evaporation on the water area corresponding to a storage of two-thirds of the maximum quantity of water stored rather than on the full area. The method suggested by Mr. Cory of considering the evaporation as part of the draft is ingenious, and seems to offer substantial advantages for use in dry climates and with long periods of depletion. For Eastern conditions, where, as an annual average, the evaporation is ordinarily less than the rainfall, but considerably exceeds it during a certain period in summer and fall, the method suggested in the paper seems to be better adapted. Mr. Hazen.

There is also the interesting case, occasionally found (not discussed either in the paper or by Mr. Cory), where the water drawn from existing lakes or reservoirs is measured after evaporation has taken place; and, where this is the case, obviously, no further allowance

* *Proceedings*, Am. Soc. C. E., November, 1913.

Mr. Hazen.

for evaporation is required in computing the supply that can be utilized from such a source. When, however, it is desired to compare the results with records of flow from streams which have not yet been impounded, allowances for evaporation are necessary in order to estimate the probable natural flow of the stream. This procedure was followed in preparing the Croton, Sudbury, and Wachusett data used in the paper.

After all, the different methods of allowing for evaporation are only different ways of doing the same thing, and, with the same fundamental assumptions, no appreciable difference in results should grow out of any reasonable variation in the method of making the correction.

It is interesting to note that further study of evaporation indicates that, in most cases, early estimates were too high. In other words, the errors in the experimental procedure have usually been in the direction of increasing the apparent quantity of evaporation.

The question of whether the land area or the total area should be used as a basis for stating run-off is one which does not affect in any way the general method proposed by the writer. It makes no difference in the final result which of the two methods is used, so long as that method is kept clearly in mind and is properly applied to the end of the calculation. The land area was selected for use by the writer, for Eastern streams, following Mr. F. P. Stearns' classic discussion of this subject, and he still believes that for these streams this method is, on the whole, rather more convenient. In other cases, it has no advantages.

Mr. Marsh's statement in regard to the mean flow of the Croton for two successive 18-year periods is interesting. Obviously, such periods of low flows must be anticipated from time to time, but how often? The method outlined in the paper gives the basis for a definite answer to this question. The coefficient of variation in annual flows of the Croton River is 0.239. The probable error in any one 18-year period is:

$$\frac{0.239 \times 0.6745}{\sqrt{18}} = 3.8 \text{ per cent.}$$

In the 18-year period from 1869 to 1886, the mean flow was 12.5% less than the record mean for the whole period. Assuming the record mean to be the true mean, the actual error for this 18-year period was 3.3 times as great as the probable error for one 18-year period. From probability tables it appears that 97.4% of all the terms in a series which follows the normal law of error, differ from the mean by less than this amount. The remaining 2.6% of the terms are outside the limits, one-half being above the upper limit and one-half below the lower one. Of all consecutive 18-year series, 1.3%, therefore, would be expected to be less than the true mean by an amount at least as great as that which this Croton series did actually drop

below the record mean of the Croton River. In other words, in any 18-year series, there is 1 chance in 77 that the mean will fall below the true mean by as much or more than the actual reported drop in this case. In an indefinitely long period of years, one such 18-year dry period would be expected once in every 77 years, on an average. The Croton records cover 46 years, to the present time. Within this record are comprised 29 periods, each having 18 consecutive years. Each of these periods had 1 chance in 77 of being below the limit. There were, therefore, 29 chances out of 77 that some one of the 18-year periods would fall short of the record mean by an amount at least equal to the shortage that is reported in this case. The probabilities are almost 2 to 1 that such a shortage will not happen in any given 46-year period. The variation in this record, although it reaches 3.3 times the probable error for any one 18-year series, is one that would have to be expected in one out of every three 46-year periods, and its actual occurrence in this case is an impressive example of the possibility of error in short-term averages. Mr. Hazen.

It is possible, of course, that in this case there may be a long-term cycle variation in rainfall and run-off which may contribute in some measure to the low average, and it may also be mentioned that the greater part of the flow in the first 18-year period was measured as flood discharge over the old Croton Dam, and the greater part of the flow in the second 18-year period was measured in the two Croton Aqueducts on its way to the city; and it may be that, notwithstanding the great care that has been exercised in adjusting the old records, some small residual error may exist and be an element in the reported difference.

Answering Mr. Mills' question, the method proposed is an elastic one and allows the degree of provision against drought to be selected. By working to the 99% year, shortages such as those which Mr. Mills speaks of will be guarded against in 99 years out of 100, though, if the 95% year is selected, a shortage must be anticipated once in 20 years. Therefore, any degree of insurance that is desired can be selected, and the calculation made accordingly.

Mr. Taylor is entirely right in calling attention to the wide difference in run-off and storage conditions between the East and the West, and it is unfortunate that these differences have been so often overlooked, and that such investments as the one which he mentions have been made on inadequate data. On the other hand, as he points out, even in the same case, a properly designed development would have in it great possibilities of good, and would no doubt ultimately prove remunerative.

Mr. Tighe has recorded the origin of the mass-curve, and it may be well to point out that the methods now proposed do not in any way supersede it. On the contrary, the mass-curve method is used as

Mr. Hazen.

a basis for computing the storages on which all the tables and diagrams in the paper are based. Practically, however, the mass-curves were not drawn, because it was found that the results might be obtained more easily arithmetically.

Mr. Tighe points out an exception to the rule that, within certain limits, storage on a tributary is substantially as useful as on the main stream. The summer refill water which he mentions, is small in quantity in the dryest years; it is much more abundant in wetter years, when it is not needed. There is no doubt that a small storage on a remote site would have reduced value because of the loss of water in transit in a dry time. With abundant gravel, water lost by percolation may be more important in this case than water lost by evaporation, and, although the former may be expected for the most part to re-appear subsequently on the main stream, it may come at a later time, when the natural flow is otherwise sufficient, and when it is not needed. So far as this is the case, the stored water will be lost and the available supply decreased. The loss of water by percolation extending to and around the intake dam is not taken into account in the method of analysis proposed in the paper. If it were desirable to consider such loss, it would seem best to regard the water lost in this way as a draft, in the same way that Mr. Cory proposes to treat the loss by evaporation.

Mr. Goodrich has suggested a possible explanation of the fact that the curves representing storage and flow data are skew curves, and do not exactly follow the normal law of error. It is his thought that the curve may be composed of several independent curves superimposed on each other. This matter is an extremely important one. It seems to carry great possibilities of improved methods of analysis. The writer earnestly hopes that Mr. Goodrich will find time to develop this method and apply it, and he suggests that this subject would be a most appropriate one for a paper to be presented to the Society.

Mr. Cory's discussion is of fundamental importance. It greatly increases the value of the paper, because it extends the use of the methods to new fields and shows their convenient and useful application. The writer regards the method as more important than the results deduced by it and presented in the paper, and he is particularly interested, therefore, in showing that it is equally applicable in California and in New England, and to problems of municipal water supply, irrigation, and power.

In some cases, at least, the actual numerical figures obtained on a general basis from the records of Eastern streams having the smallest variations in their annual flows are found to be substantially equal to like figures obtained by applying the same methods to Southern California streams having the greatest variations in their annual flows. This coincidence is striking, and it cannot fail to add con-

fidence to the use of the method for all intermediate conditions, and these include most of the cases that occur. It was the intention to make the methods general in form, so that they would have wide application, but the discovery that both the method and the figures in some of the diagrams do apply to such widely different conditions as those of Southern California is most gratifying. Mr. Hazen.

Fig. 30 is extended far enough to include all the storage ordinarily used, or that will ordinarily be desired on such Eastern streams as serve as the basis of the study; but, in California, where water is relatively more valuable, and where cheap storage sites are found, the economical limit of storage is moved upward many times, as is also shown in Mr. Le Conte's discussion; and many of the larger water projects in successful use in California at the present time will be found to be beyond the limits represented by Fig. 30. The extension of the study to these higher relative storages, therefore, is desirable and necessary. Mr. Cory, using California data, has extended it in this way.

The writer has checked Mr. Cory's results by an independent study of some California data and by extending the Eastern results, and he is satisfied of their substantial accuracy. For the lower relative storages and rates of draft, the Eastern data presented in the paper are adequate to determine the required storage with a fair degree of certainty, and they are better suited to this use than Mr. Cory's California records. On the other hand, the California data for the higher rates of draft are better than the Eastern data, and are to be preferred. The combination diagram (Fig. 38) which Mr. Cory has prepared, therefore, is a safer one to use than could have been deduced from either set of data taken by itself. The fact that the two sets of data produce results which check at the point of junction, both in position and in direction, is most satisfactory.

It is not to be supposed that the storage ratios for the highest rates of draft can be determined with the same degree of accuracy that is reached with the lower ones. With a draft equal to $1 - 0.4C$*, which was the highest limit investigated with the Eastern data, there will be, on an average, a period of about 9 consecutive years in each 20 when there is no overflow. With the records covering 20 or 30 years, and in a few cases somewhat longer periods, this is about as far as the analysis can be carried without sacrifice in accuracy. With the greater draft of $1 - 0.2C$ and $1 - 0.1C$, considered by Mr. Cory, and necessary to include California data and conditions, the normal periods of depletion are greatly extended, until the normal condition of the reservoir becomes one of being only partly full. It is the exception, perhaps the rare exception, when the water reaches the overflow. This condition is actually reached in many California reservoirs

* Mean flow multiplied by 1 less 0.4 coefficient of variation.

Mr. Hazen.

at the present time. The greatest normal period of depletion in a 100-year period may rise to 40 or 60 years, or more. It is obvious that records of streams covering only 20 or 30 years are inadequate to establish with certainty the full storage required for these higher rates of draft. The writer, therefore, regards the figures in Mr. Cory's extended diagram (Fig. 38) as approximations, which are the best available at the present time, but are certain to be modified more or less when more extended data become available.

The question may also be considered whether, by mathematical methods and a better analysis of the probabilities of the situation, it may not be possible for some one to reach a better understanding of the matter than the writer has been able to do.

To give Mr. Cory's extended diagram (Fig. 38) full use, and to show its application, not only to California streams, but to many others having higher coefficients of variation than any that were discussed in the paper, the writer presents Figs. 40 and 41, as representing the storage required to maintain the supply in 95% and 98% dry years for California and other similar conditions. These diagrams are based on Mr. Cory's extended diagram (Fig. 38) with a curve for monthly and daily storage based on some studies by the writer of a few California streams. It is the writer's belief that this will be found to fit well enough to be used with advantage in estimating storage in a great variety of climates. It is especially applicable where the variation in annual flows is greater than that for Eastern streams, and where the seasonal fluctuation in flow is also greater. Figs. 40 and 41 also differ from Figs. 33 and 34 in extending much farther upward, to cover streams with greater variations in flow, and with the use of greater relative storages.

The most careful and conservative estimates of public water supplies for Eastern cities in the last decade have been based on assumptions substantially as severe as those corresponding to a 98% dry year. It is the writer's opinion that the 95% year will be more generally applicable, and, on the whole, is a better basis for rating works. If a basis were used corresponding to the 95% year, and it were wrongly assumed that it represented the dryest year to be expected, great damage might follow, but if the limit is recognized and kept always clearly in mind, the likelihood of harm will be largely eliminated. The use of the term, 95% dry year, is in itself a constant reminder that 1 year in 20 will probably be dryer than it, and therefore tends to safety. On the other hand, to limit the rating of works by using the 98% year as a base has the effect of reducing the available supply so much that all of it can be used on an average only once in 50 years, and this will seldom be justified.

The writer regrets Mr. Cory's difficulty in understanding portions of the paper. This may be due to the writer's effort to compress the

Mr. Hazen.

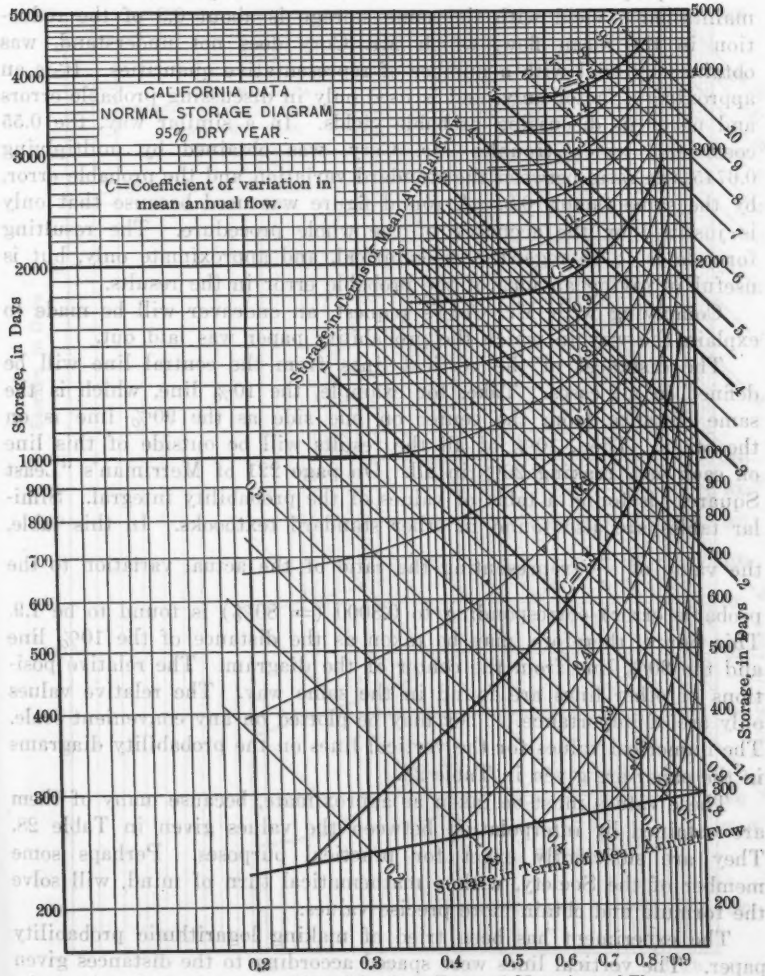

FIG. 40.

Mr. Hazen. material so as to keep the paper within reasonable limits of length, and to avoid making it a treatise on least squares and statistics, and covering ground better covered in textbooks on those subjects.

The proposition that above the critical storage the reduction of maintainable yield with the same storage is about 0.8 of the reduction in the mean flow, which Mr. Cory does not understand, was obtained by trial with a number of representative quantities. It is an approximate factor only, and is used only in discussing probable errors and never in discussing probable yields. In a similar way, the 0.55 coefficient, which troubles Mr. Cory, was obtained by multiplying 0.6745, the ratio between the standard variation and the probable error, by the same factor, 0.8. A round figure was used because that only is justified by the accuracy of the whole procedure. The resulting formula is to be regarded as empirical, and approximate only, but is useful in giving an idea of the probable error in the results.

Complying with Mr. Cory's request, an endeavor will be made to explain the way in which the probability paper was laid out.

The distances of the vertical lines from the central line will be defined in all cases. Take, for example, the 10% line, which is the same distance from the center on one side as the 90% line is on the other. Then, 10% of all the results will be outside of this line on each end, making 20% in all. On page 221 of Merriman's "Least Squares" is found a table of values of the probability integral. Similar tables are also found in other standard textbooks. In this table, the value of $\frac{x}{r}$ (representing the ratio of the actual variation to the probable error) corresponding to 0.8000 (= 80%) is found to be 1.9. This figure, therefore, may be taken as the distance of the 10% line and the 90% line from the center of the diagram. The relative positions of other lines are found in the same way. The relative values only are of importance. They may be plotted on any convenient scale. The numerical values for the vertical lines on the probability diagrams in the paper are given in Table 28.

These values must be taken as approximate, because many of them are obtained by interpolation between the values given in Table 28. They are sufficiently exact for practical purposes. Perhaps some member of the Society, with a mathematical turn of mind, will solve the formula and obtain more precise values.

The experiment has been tried of making logarithmic probability paper. The vertical lines were spaced according to the distances given in Table 28, and the horizontal lines were on a logarithmic scale. Numbers plot in a straight line on such paper when their logarithms form a true probability series. Logarithmic probability paper has been found helpful where the degree of skewness in the curve is very great. For the flow and storage data used in the paper, the

Mr. Hazen.

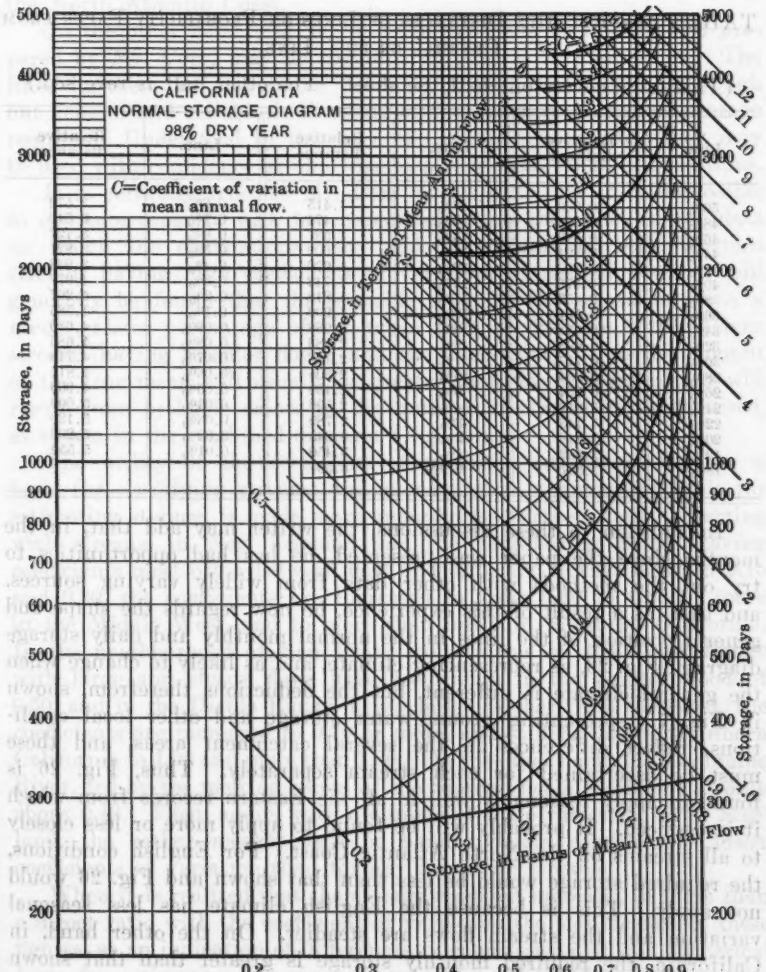

FIG. 41.

Mr. Hazen.

arithmetic probability paper has proved more satisfactory. For some other investigations the logarithmic probability paper has seemed to be better.

TABLE 28.—RELATIVE DISTANCES OF LINES ON PROBABILITY PAPER FROM CENTRAL OR 50% LINE.

(This table covers one-half the sheet. The other half is reversed.)

Line.	Relative distance.	Line.	Relative distance.	Line.	Relative distance.
50%	0.000	17%	1.415	0.8%	3.573
48%	0.074	16%	1.474	0.7%	3.646
46%	0.149	15%	1.537	0.6%	3.727
44%	0.224	14%	1.602	0.5%	3.821
42%	0.300	13%	1.670	0.4%	3.933
40%	0.376	12%	1.742	0.3%	4.077
38%	0.453	11%	1.818	0.2%	4.267
36%	0.531	10%	1.900	0.1%	4.585
34%	0.611	9%	1.988	0.09%	4.630
32%	0.693	8%	2.083	0.08%	4.685
30%	0.777	7%	2.188	0.07%	4.748
28%	0.864	6%	2.305	0.06%	4.817
26%	0.954	5%	2.439	0.05%	4.900
24%	1.047	4%	2.596	0.04%	5.000
22%	1.145	3%	2.789	0.03%	5.120
20%	1.248	2%	3.045	0.02%	5.290
19%	1.302	1%	3.450	0.01%	5.550
18%	1.357	0.9%	3.507		

In addition to these discussions, the writer may add that, in the months since the paper was presented, he has had opportunities to try out the methods with other data from widely varying sources, and that, as a result of this experience, he now regards the shape and general position of the lines in the normal monthly and daily storage diagram, Fig. 26, as representing climate, and as likely to change when the general climate is different, but the deductions therefrom, shown in Fig. 7, representing ground-water storage and other local conditions, reflect differences in the several catchment areas, and these must be ascertained for each stream separately. Thus, Fig. 26 is found to apply reasonably well to all the Eastern records from which it is deduced. It probably will be found to apply more or less closely to all streams on the North Atlantic Coast. For English conditions, the required storage would be less than that shown and Fig. 26 would not apply. This is because the English climate has less seasonal variation and the stream flows are steadier. On the other hand, in California, the required monthly storage is greater than that shown by Fig. 26. This figure, therefore, may be accepted only for the general region from which the data were obtained.

For other climatic conditions, the local data could be made to furnish, by the methods described on pages 1950 to 1977,* a diagram of normal daily and monthly storage for local use.

* *Proceedings*, Am. Soc. C. E., November, 1913.

Mr. Hazen.

As Fig. 26 serves as the base of Figs. 33 and 34, these diagrams should also be regarded as only strictly applicable to regions where the general climatic conditions do not differ widely from those on the North Atlantic Coast.

On the other hand, Fig. 30, and the extension of it (Fig. 38) prepared by Mr. Cory, may be regarded as general in application. The lines in them are not to be taken as precise, but rather as rough but general and reliable indications of the quantity of annual storage required. Understood in this way, the writer believes that they may be used with confidence as applying to a very wide range in conditions.

It is certainly true, as Mr. Cory points out, that it is impossible to estimate capacity with less percentage error than that in the data on which the calculations rest; and, in connection with Western streams having high coefficients of variation in annual flows, it will generally be found that the probable error of the record mean is a much greater percentage of the mean than is the case with Eastern streams having steadier flows; and the uncertainty as to the amount of the true mean will usually be greater than any difference that will result from probable errors in the number of storage units required, as shown in the combined diagram (Fig. 38).

The utility of the coefficient of variation in annual flow as a basis for classifying streams and as serving as a numerical basis for estimating storage, is made more apparent by further study. Starting with streams in New England and the neighboring States having coefficients most often between 0.20 and 0.25, and always between 0.15 and 0.30, the coefficients are increased to from 0.40 to 0.60 or more in the Middle West, and to more than unity in Southern California. In the neighborhood of San Francisco, streams on the Coast Range with large and steady flows have coefficients in the neighborhood of 0.50, and in the Diablo Range, a few miles farther from the coast, the coefficients are increased to 0.70 or more, and still farther in Southern California to 1.00 and more than 1.00. On the other hand, the Tuolumne River, fed by the melting snows of the Sierras, has a coefficient of only about 0.42. Then, again, with a climate of little variation, as in England, the rather meager data at hand indicate considerably lower coefficients of variation than for any American streams.

When it is realized that the storage required increases in more than a direct ratio with the coefficient of variation, the significance of these figures, as an indication of differences in conditions, and as a numerical basis for estimating the storage required in the different cases, may be realized.

As Fig. 26 serves as the base of Figs. 33 and 34, these diagrams should also be regarded as only strictly applicable to regions where the general climatic conditions do not differ widely from those on the North Atlantic Coast.

On the other hand, Fig. 30, and the extension of it (Fig. 35) prepared by Mr. Cory, may be regarded as general in application. The lines in them are not to be taken as precise, but rather as rough but general and reliable indications of the quantity of annual storage required. Understood in this way, the writer believes that they may be used with confidence as applying to a very wide range in conditions.

It is certainly true, as Mr. Cory points out, that it is impossible to estimate capacity with less percentage error than in the data on which the calculations rest; and, in connection with Western streams having high coefficients of variation in annual flows, it will generally be found that the probable error of the record mean is a much greater percentage of the mean than is the case with Eastern streams having steadier flows; and the uncertainty as to the amount of the true mean will usually be greater than any difference that will result from probable errors in the number of storage units required, as shown in the combined diagram (Fig. 38).

The utility of the coefficient of variation in annual flow as a basis for classifying streams and as serving as a numerical basis for estimating storage, is made more apparent by further study. Starting with streams in New England and the neighboring States having coefficients most often between 0.20 and 0.35, and always between 0.15 and 0.50, the coefficients are increased to from 0.40 to 0.60 or more in the Middle West, and to more than unity in Southern California. In the neighborhood of San Francisco, streams on the Coast Range with large and steady flows have coefficients in the neighborhood of 0.50, and in the Diablo Range, a few miles farther from the coast, the coefficients are increased to 0.70 or more, and still farther in Southern California to 1.00 and more than 1.00. On the other hand, the Truckee River, fed by the melting snows of the Sierras, has a coefficient of only about 0.42. Then, again, with a climate of little variation, as in England, the rather meager data at hand indicate considerably lower coefficients of variation than for any American streams.

When it is realized that the storage required increases in more than a direct ratio with the coefficient of variation, the significance of these figures, as an indication of differences in conditions, and as a numerical basis for estimating the storage required in the different cases, may be realized.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

GROUTED CUT-OFF FOR THE ESTACADA DAM.

Discussion.*

By Charles H. Paul, M. Am. Soc. C. E.

Mr. Paul.

Charles H. Paul, M. Am. Soc. C. E. (by letter).—The author has presented much interesting information, and there is no doubt that this paper, together with the discussions that it calls forth, will prove a valuable addition to engineering literature.

Foundation grouting is being carried on in connection with the construction of the Arrowrock Dam, and, although conditions there are not comparable with those at Estacada, a brief discussion of methods and results may be interesting in connection with the general consideration of this subject.

The Arrowrock Dam is a concrete masonry structure of the gravity type, 350 ft. high. The general level of the foundation in the canyon section is about 80 ft. below the river bed, and reaches a depth of 90 ft. at the deepest point. The foundation is a firm, hard granite. The rock is free from evidences of faulting, crushing, or shearing, but is characterized by rather frequent parallel joints giving it a sheeted structure which has a general north and south (across-canyon) trend, and a high dip up stream. On account of the unusual height of the dam, it was desired to take every precaution to prevent excessive seepage or the accumulation of upward pressure. Therefore, it was decided to grout the foundation and abutments along the up-stream face, although it was believed at the start that the character of the rock was such that the seams would take very little, if any, grout. In other words, this grouting was looked on from the beginning simply as a precautionary measure, and it was believed that the integrity of the structure would not be affected seriously by the success or failure of the grouting operations.

* Continued from May, 1914, *Proceedings*.

Mr. Paul.

Along the up-stream face, a cut-off channel, or keyway, with a minimum depth of 10 ft., was cut out of the bed-rock, and the grout holes were drilled from the bottom of this channel to a depth of 25 or 30 ft., thus making the bottom of the holes from 35 to 40 ft. below the general level of the foundation. Two rows of holes were drilled, 5 and 13 ft., respectively, inside the line of the up-stream face of the dam, and the longitudinal distance between the holes in each row was 10 ft., with the holes in the two rows staggered.

At the beginning of the work, these holes were drilled before the rock was covered with concrete, and were brought up through the concrete, by a 3-in. wrought-iron pipe, to the elevation from which they were grouted. This pipe was set in such a way that, when grouting, the mixture could flow freely into any seam that might exist between the concrete and the rock. It was realized at the time that the most approved method for work of this nature was to drill and grout a hole before another hole was drilled in that immediate vicinity, but that plan was not followed in this case for two reasons: First, the absence of large seams and the apparent tightness of the existing seams in the bed-rock appeared to make it unnecessary to carry out the work in this manner; second, bed-rock was not uncovered until late in the fall, and as the season for placing concrete was nearly over, and it was most desirable to have the bed-rock covered with concrete before winter set in, it was necessary to push the concreting without any loss of time. Later developments proved that in this case this method of grouting was justified, as in only a very few cases, when the leakage test was applied to the hole before grouting, was there any connection between the hole tested and adjacent holes. In the few cases of this kind that did occur, a satisfactory job was obtained by grouting the two or three connecting holes in as close succession as possible, and capping the other connecting holes while one was being grouted.

During the early part of the work Burley drills were used. Later, after the foundation had been covered and the grouting operations were carried on up the abutments, pipes were set in place at the location of the holes and the holes were drilled through these pipes with a diamond drill, after a sufficient depth of concrete had been placed around them. The practice was then adopted of drilling and grouting a hole before the next one was drilled, but, on account of the tight condition of the rock, there was very little difference between the results obtained by the two methods.

The grouting machine was of the same type as that used at Estacada. The cement was a 45% blend of sand-cement (45% of granite and 55% of Portland cement), ground to such a fineness that 90% would pass the No. 200 sieve. The grout was mixed in proportions of about 1 part cement to 5 parts water, except in a few cases, when it was thickened up to about a 1:3 mixture. Pressure for the leakage

test and for final application on the grout, was obtained from a tank set at an elevation of about 15 or 20 ft. above the level of full reservoir. Air for the operation of the grouting machine was obtained from the main compressor plant, and gave a pressure of about 95 lb. at the machine, which, however, was set at an elevation considerably above the bottom of the hole, so that the pressure at that point was in the neighborhood of from 150 to 160 lb. for the lowest holes. Mr. Paul.

Before making the leakage test, immediately prior to grouting, each hole was carefully washed out and sounded; then the leakage test was applied from the elevated tank. The tank was graduated to indicate gallons, and the leakage test was applied to each hole, under full pressure, for a period of at least 10 min. As was expected, most of the holes showed practically no leakage before grouting, and took only about enough grout to fill the hole. In a few cases, however, an appreciable leakage was detected, and some grout was forced into the rock, although up to date the maximum quantity of cement forced into any one hole has been only about 3 bbl. To practically all the holes full air pressure was applied at the beginning, but, in a very few instances, it was found more advantageous to begin with a pressure of about 25 lb. and increase this gradually to the maximum as the hole tightened. When a hole would take no more grout, the water pressure from the tank above the dam was applied—with the idea of driving the grout home—with a pressure in excess of that which would develop from a full reservoir. At the time of this second application of water pressure, careful measurements were taken at the tank in order to make sure that the hole was tight before removing the grouting apparatus.

As to the success of the operations at Arrowrock, there is direct evidence in at least two unrelated instances that the grouting is accomplishing the results expected. At one point, near the bottom of the north abutment, where several adjacent holes showed an appreciable leakage before grouting, it was decided to drill and grout some additional holes before the pumps were pulled and the water allowed to rise to the river level. These holes were drilled with a diamond drill, from just outside the up-stream face of the dam, and were given a slight inclination, so as to bring the bottom of the hole well under the dam and in the region covered by the previous grouting operations. They were spaced so as to pass between the holes already grouted. Most of these holes were drilled to depths greater than those of the original holes, and each hole was grouted before the next one was drilled. Without exception, it was found that these holes were practically tight when the leakage test was applied, proving without question that the earlier grouting operations had tightened up the foundation successfully.

In another case, in excavating the keyway up one of the abutments, some seamy rock was encountered, which had been affected by previous grouting operations, and in the excavation of this rock, it was noted

Mr. Paul.

that the seams were completely filled with grout. In some cases, cracks which otherwise could hardly have been detected, could be followed by the exceedingly thin line of grout that marked them, resembling more than anything else a fine, sharp, pencil line. This grout was encountered at an elevation of at least 60 ft. above where the grouting machine had been located, showing that the grout, in this case, at least, had traveled for a long distance and had filled the seams very thoroughly.

As to the general success of grouting operations, it is believed that so much depends on local conditions that it is impossible, in any given case, to predict just what the results may be or how far they may be relied on. It seems to the writer that a hard rock with fairly continuous seams presents ideal conditions for grouting operations, as long as the surface seams may be sealed off so that the grout may be forced down and out, rather than up to the surface, where it can escape freely. Loose gravel or sand is the other extreme, and it is very doubtful if such material can be grouted successfully. In fact, the writer has not yet heard of an instance where this has been done. All grades of material between the two may be encountered, in which grouting will give more or less satisfactory results.

The writer is of the opinion that grouting, as a precautionary measure, is excellent treatment for the foundation of any dam of considerable size, but where the safety of the structure depends on the success of the grouting operation, it would be unsafe to go ahead with construction until after grouting had been tried and proven effective. In other words, where grouting is actually needed, it is unsafe to depend on it, except after convincing evidence, at the site, that it will give the results desired.

AN INVESTIGATION OF SAND-CLAY MIXTURES FOR ROAD SURFACING.

Discussion.*

By John C. Koch, Assoc. M. Am. Soc. C. E.†

Mr. Koch.

John C. Koch, Assoc. M. Am. Soc. C. E. (by letter).—Mr. James seems to be under the impression that the writer's investigations and studies of sand-clays were confined to those of a restricted area in North Georgia, and that the sands prevalent were "the Orangeburg sands of the Lafayette formation". For the purpose of making clear that typical sand-clays, representative of the entire State of Georgia, were examined, it may be sufficient to state that analyses were made from numerous samples from 23 counties lying in the Coastal Plain, from 5 counties along the Fall Line, and from 20 counties in the Piedmont Region. The writer has not been able to find any geological account of the existence of the Orangeburg sands of the Lafayette formation in the northern third of Georgia, which is almost altogether of igneous and metamorphic character and is often referred to as the Crystalline Area. According to Professor S. W. McCallie, State Geologist of Georgia, the Lafayette formation is found only on the Coastal Plain, and has probably been confused with certain red sands and gravels of the Eocene and Cretaceous formations, also occurring there. As is generally known, the sand-clays of the Crystalline Area give far better results in road work than those of other formations, the sands of the Lafayette formation being only of minor importance.

The road problem of the Coastal Plain along the Atlantic seaboard is how to overcome the difficulties incident to a surface soil composed largely of very fine sand. It is often possible to find a fair supply of clay a few feet below the surface. This may contain from 20 to

* Continued from May, 1914, *Proceedings*.
† Author's closure.

Mr. Koch.

60% of fine sand. If such material is used, it generally produces fair results, and is certainly much better than the sand road. With reference to the case where the sands are floury and the clays run high in fine-grained sand, an alleviation of sand-road conditions may easily be made with this material. The writer, however, would hesitate to present this as a desirable or satisfactory criterion for sand-clay roads in general.

The simple field tests described by Mr. James, in mixing sand and clay, are applicable, of course, only to cases where artificial mixtures are to be made. These and similar tests have been considered by the writer, but his experience has been that small spheres of the same mixture gave widely variable results, due to different percentages of moisture held in the material. By heating the spheres on a sand bath at 100° cent. until they are of constant weight, the results will be more uniform.

Mr. Blanchard's suggestion that more detailed information relative to the traffic on the various types of roads discussed in the paper would be of value to road engineers, is concurred in by the writer. Probably no subject in road literature is more difficult of adequate statistical treatment than that of traffic. A traffic census will show great fluctuations in weekly as well as monthly averages, and a census taken before and after road improvement will usually show a greatly increased traffic after such improvement. The improvement of a road often increases the traffic on that road without, apparently, affecting other roads adjoining it.

TABLE 5.—TRAFFIC ANALYSIS OF SAND-CLAY ROADS.

(Approximate.)

Type of vehicle.	AVERAGE DAILY NUMBER OF VEHICLES (BOTH WAYS).											
	Jan.	Feb.	Mar.	April.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.

Table 5 is presented in order to give an idea of the average traffic conditions prevailing on the sand-clay roads of Georgia. It shows

the daily average number of vehicles going to and from a typical county seat or shipping point, over a single road, during each month. Traffic to and from larger cities, of more than 20 000 population, is not considered in this table. On some of the sand-clay roads, the traffic will average less than that given in Table 5, and on about 20% of the mileage the number of vehicles of each class may be three times as many. These figures are based on traffic studies made in many counties of Georgia, and are substantially correct in so far as it is possible to prepare average figures from such data. The ratio of motor-driven to horse-drawn vehicles will undoubtedly steadily increase. Mr. Koch.

The following memoranda concerning the actual loads carried may be of interest in connection with Table 5:

One-horse vehicle, average net load,	750 lb.
Two-horse " " " "	1 500 "
Four-horse " " " "	3 000 "
Motor trucks, " " "	1 500 "

Climatic conditions in Georgia vary considerably, from the southern portion, not far above sea-level, with a very mild climate, to the northern boundary, in the Blue Ridge Mountains, at an elevation of from 600 to 1 500 ft. above sea-level, with a much more rugged climate. Generally, the inferior natural sand-clays are found in the southern part of the State, where the climate is very mild. As a rule, the best and most durable sand-clays are found chiefly in the northern half of the State. In the latter section the winters are not severe, but the ground freezes and thaws all through the winter, so that the tendency to disintegrate the sand-clay surface is possibly as severe in the aggregate as the spring thaw in the more severe climate of the Northern States.

The writer has examined sand-clay road surfaces during the winter, and has studied the effects of the alternate freezing and thawing, for the purpose of arriving at some basis for determining their suitability for withstanding severe freezing and thawing. On the better sand-clay roads the effect of weeks of freezing and thawing was to produce a thin layer of slushy material, from ½ to 1 in. thick, below which the mixture was quite firm and impervious. In a number of such instances, the writer has cleared off the slushy material and carefully cut down through the surfacing which was almost always found to be very dense and hard and to contain scarcely any more moisture than in summer. Where mixtures of the type classified as "Hard" by the writer (in Fig. 1) were used, on removing the surfacing as described, the roadbed beneath the sand-clay was found to be as dry as it would have been in midsummer, if protected by the sand-clay surfacing. This seems to prove that impermeable mixtures should be

Mr. Koch.

used to protect the sub-grade properly, in severe climates. In making examinations of these road surfaces, areas several feet square were taken along the center line as well as in the wheel tracks, so that, as far as possible, freak conditions were eliminated.

Another point which Mr. Blanchard raises is well worthy of further study, namely, the effect of different percentages of sand-clay mixtures retained on the 10-mesh sieve, when such mixtures are used under various climatic and traffic conditions. The writer has not had opportunity to study a sufficient number of such cases to feel warranted in stating any conclusions at this time. It is safe to say, however, that, in a sand-clay mixture, the greater the proportion of material coarser than that retained on a 10-mesh sieve, the greater its durability and the more suitable its use for service in a very cold climate, provided, of course, that the coarse material is firm and hard and similar to quartz or other hard rock.

The writer agrees with Mr. Blanchard that many highway engineers will disagree with him in dividing gravel and sand on the basis of the material retained on or passing the 10-mesh sieve. The writer has used the 10-mesh sieve arbitrarily as the dividing line between sand and gravel. The following is the definition* of gravel as officially adopted by the American Railway Engineering and Maintenance of Way Association:

"Gravel is defined as small worn fragments of rock occurring in natural deposits, that will pass thru a 2½-in. ring and be retained upon a No. 10 screen."

In the writer's experience in testing sand-clays, the 10-mesh sieve has been very satisfactory as a basis for separating the coarser material from the finer. If the 4-mesh sieve had been used in analyzing the coarser materials, probably not more than 1% of the samples examined would have left any gravel on this sieve. Practically all the material classified by the writer as gravel was larger than 10-mesh size and smaller than 4-mesh size, with the single exception of Sample No. 223. This sample contained 34% of material coarser than 10-mesh size, and one-half of this was larger than 4-mesh size.

Mr. Stewart mentions the application of hot oil to the roads of the Parkway Systems of Greater New York, which were built of Hudson cementitious gravel. Similar treatment has been proposed for sand-clay roads in certain counties of Georgia, but it has not been attempted on account of the relatively great expense. The cost of a seal coat of hot oil is as great as the total cost of the sand-clay surfacing, and the only advantage that could be claimed to accrue from the additional expenditure would be a slight diminution of the dust from automobile travel. The quantity of dust raised on sand-clay

* American Civil Engineers' Pocket Book, p. 169.

roads by automobiles depends largely on the character of the construction. Well-constructed roads of a good class of this material yield from one-fifth to one-tenth of the dust that is raised on a water-bound macadam road under the same traffic conditions. Mr. Koch.

Mr. Owen's experience with artificial mixtures of sand and clay illustrates a common difficulty in making such mixtures. If natural sand-clay mixtures are available locally, but are not suitable for use alone, because of a deficiency in either the sand or clay content, this defect may be corrected by the addition of the proper quantity of sand or clay. This method of treatment will generally be found to be more economical than an attempt to build up an artificial mixture by using sand as a basis and adding the proper quantity of clay and mixing. Occasionally, it may be possible to combine two natural mixtures in which an excess of sand occurs in one and an excess of clay in the other. To determine the proportions in which such materials should be used, one may make analyses of the materials and plot curves showing their composition. Usually an inspection of these curves will suggest approximately the proportions in which the materials should be used to obtain the best results. Trial mixtures of the two materials may be studied by plotting the analyses of such mixtures, using as a criterion by which to judge their value, the analyses of sand-clays of known value. Fig. 1 has been used in this manner by the writer with excellent results.

The advantage of using a natural sand-clay as the basis for artificial mixtures lies in the fact that the two materials are somewhat thoroughly mixed, and the incorporation of the additional sand or clay required will be much more easily effected than where none of the mixing has been previously performed by Nature. In making an artificial mixture, using sand as a basis and adding the requisite quantity of clay, the latter forms in clods and balls, and thorough incorporation of the two is accomplished only by a long-continued process of puddling.

The effect of climatic conditions on sand-clay roads has been suggested by Mr. Blanchard and Mr. Owen. In regard to the effect of the severe weather conditions of the Northern States, the writer has no definite information. The following mileages of sand-clay roads were reported* in 1909 for the States named:

Connecticut	1 214
Delaware	6
Georgia	4 326
Idaho	398
Iowa	575
Kansas	202

* *Bulletin* No. 41, U. S. Office of Public Roads, p. 42.

Mr. Koch.

Michigan	2 381
Minnesota	1 051
Oregon	345
Rhode Island	6
South Dakota	129
Washington	1 223
Wisconsin	1 013
Total, leaving out Georgia.	8 543

From the foregoing, it appears to the writer that there is a considerable mileage of roads of this type in use in the Northern States, and that since 1909 there should have been developed among road builders in the States named a large amount of valuable information regarding the use and possibilities of sand-clay road construction. The total mileage of such roads in the United States reported for 1909 was 24 601, so that more than one-third of the entire mileage reported in that year was in what may be called the Northern States.

The writer wishes to call attention to the experiences of several counties, that are of interest because of the great contrast they afford in the economy of sand-clay road construction as compared with water-bound macadam. Therefore, the following examples are presented for consideration.

Habersham County, Ga.—A macadam road was laid in 1909, if the writer has been correctly informed, at an expense of about $2 000 for a length of 2 000 ft. This road was 25 ft. wide, and had field-stone curbs. The macadam was about 5 in. thick after rolling. In 2 years the road had become so rough as to be avoided by the traffic whenever the parallel side streets were not too muddy. In 1912 a new road was built of a natural sand-clay mixture, extending from the end of the old macadam section mentioned, to the railroad station at Clarkesville. This was curbed with field stone, and cost $1 200 per mile. It is smoother after a year's service than the macadam road ever was, and is easily kept in excellent repair on account of the large quantity of good sand-clay close at hand.

Hall County, Ga.—In the period, 1905 to 1908, this county established quarries, installed machinery of all sorts for road-making, and spent about $40 000 in building water-bound macadam roads. The rock used was a local gneiss. The roads, for the most part, were surfaced 5 in. thick and for a width of 20 ft. The total length actually constructed was between 8 and 10 miles, as nearly as the writer can learn. The total road mileage of this county is about 900, of which probably 200 miles would serve 50% of the traffic. From this it can be readily seen how impossible it would be to construct the most important roads with macadam. The average annual income from taxes for road improvement in this county is about $15 000.

Mr. Koch.

In the fall of 1911 almost all the macadam roads which had been constructed were in such bad condition that reconstruction seemed absolutely necessary. To reconstruct these roads with macadam was a sheer financial impossibility, as the county was still in debt for the original construction and equipment. Temporary repairs were made, which rendered the roads passable that winter. In the fall of 1912, the writer was consulted by the county authorities as to what could be done to improve road conditions, and as to the adoption of a definite low-cost programme that was financially feasible. After an examination of the macadam and other roads, all of which were in wretched condition, especially the former, the writer recommended the adoption of the sand-clay road wherever that material could be used without excessive expense. After sampling a number of large areas of natural topsoil sand-clay, the writer found that, with few exceptions, excellent natural mixtures were readily available with short hauls; so that almost all the important roads were favorably situated for reconstruction with these mixtures. It was also found that the deep holes in the macadam roads could be filled with the sand-clay, which bonded well with the macadam, and, at comparatively small expense, many of these roads were thus repaired. The remainder was plowed up and loosened and then a 10-in. layer of sand-clay was placed over it and compacted by the traffic. Since then the county has carried out a consistent policy of repairing old macadam with sand-clay until the macadam is worn out, and making all new construction of sand-clay. Under this new policy, 20 miles of new sand-clay roads have already been constructed, at an average cost of about $425 per mile; the old macadam is still giving some service, and the improved roads are passable at all seasons of the year. All the expenses incident to this new policy have been met by current revenues.

Clarke County, Ga.—The experience of this county was somewhat similar to that of Hall County, except that sand-clay construction has been in use here for nearly 7 years. During the period, 1905-08, Clarke County spent about $50 000 on the construction of 7 or 8 miles of water-bound macadam roads. This had been accomplished in a little more than 3 years. Then it became evident that the cost of maintenance was a far more serious item than had been thought. It was so great that it soon became clear that macadam was too expensive an investment for the county's revenues.

In 1907, Mr. W. H. Holman, Superintendent of County Roads, began experimenting with natural mixtures of sand-clay, taken from the surface of cultivated fields, as a road-surfacing material. This material is often referred to as "topsoil". The experiments were so successful that topsoil was soon adopted as the surfacing material for all roads, and by 1913, practically all the important roads of the

Mr. Koch.

county had been surfaced with it, for a total length of 100 miles. This large mileage was built with current revenues (approximately $20 000 annually), without a bond issue or the assumption of a heavy burden of taxation. This splendid work has been brought about largely as a result of the untiring efforts of C. M. Strahan, M. Am. Soc. C. E., who, as County Engineer, has been identified with this road work for many years.

The average annual cost per mile of the macadam roads built by this county, including bond interest, sinking fund, and maintenance, was found to be about $1 200 (neglecting the fact that after from 4 to 6 years of service they were covered with topsoil to prevent complete raveling and destruction).

The cost of sand-clay roads in this county has averaged about $500 per mile, so that the annual cost of 1 mile of macadam (neglecting depreciation entirely), was sufficient to build 2.4 miles of new sand-clay road. The cost of maintenance of sand-clay roads of good quality is very low, averaging $5 per mile per annum in this county. Poorer qualities of sand-clay can be kept in excellent condition at an expense of from $10 to $30 per mile per annum depending on its quality and the character of maintenance required.

In conclusion, it should be stated that the specific cases just described are presented as concrete examples of typical experiences in many parts of the South, and that these cases are not referred to in any spirit of criticism, but for the purpose of emphasizing the fact that, in many parts of the United States in which the principal, but not the only, difficulty has been poverty, sand-clay offers the only feasible solution of the road problem. There are many counties where the mileage of public roads is so great that there is a mile of road for every three to ten voters. It is especially for such sparsely settled districts that the improved low-cost road is a necessity. Though the sand-clay road is adapted to the heavy traffic of much more densely settled communities than those indicated, it also offers to sparsely settled communities hope of improved roads without an excessive burden of taxation.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

THE DETERMINATION OF SAFE YIELD OF UNDERGROUND RESERVOIRS OF THE CLOSED-BASIN TYPE

Discussion.*

BY MESSRS. JAMES OWEN AND G. E. P. SMITH.

Mr. Owen.

JAMES OWEN, M. AM. SOC. C. E.—Although Mr. Lee's paper is confined somewhat to underground water supplies in the western part of the United States, a great deal of investigation has been done and a great deal of money has been spent and wasted on such supplies in the eastern sections and in localities near New York City, and it seems that if it were possible in the future to define certain rules and principles governing the question of getting water from the ground, it would be better for everybody.

The section around New York has a variety of topographical and geological conditions. According to the speaker's idea, the underground supplies can be defined under about four heads, that is, the original sandstone deposition, prior to the volcanic upheaval; the volcanic upheaval of gneiss in Westchester County and New York, and the trap in New Jersey; the glacial and post-glacial depositions, and, incidental to these, the terminal moraines; and finally, in lower New Jersey, what might be called the post-tertiary deposition. The first and the last, the original sedimentary deposition of the sandstone and the post-tertiary deposition, have fairly well-defined radii of supply.

It is well known that water can usually be obtained by driving through sandstone. In New Jersey, if one drives through certain strata, water can be obtained, and an interesting incident was shown

*This discussion (of the paper by Charles H. Lee, Assoc. M. Am. Soc. C. E., published in April, 1914, *Proceedings*, and presented at the meeting of May 6th, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Owen.

when Asbury Park, N. J., desired a water supply and was advised by Professor Gay, State Geologist of New Jersey 30 years ago, to go down 800 ft., at which depth all the necessary water could be obtained. On trial, water was found within 40 ft. The final result has been that all through that shore territory the supply of water has been ample, good, and economical. In this section, however, the main consumption has only lasted about 4 months in the year, and during the other 8 months, the disposal of the underground supply would have failed to be profitable for steady communities.

In the sandstone formation, a good and reliable supply can always be obtained, subject to the chemical and natural properties of the water. In New Jersey, wells have been sunk 400 or 500 ft. below tidewater and ample water has been found, but its chemical constituents have made it rather detrimental for public use. In one case, where the well was put down 400 ft., the deposition of lime was about 8 in. in 4 months. That, of course, debarred its use for public purposes. The water, however, was storage water, and the slow percolation through the sandstone had not allowed for a free flow; consequently, the chemical deposition ensued.

In the other two regions, the volcanic and the post-glacial formations, there is a certain amount of uncertainty in regard to the supply. In the volcanic formation with a slight cover, of course, there is no water unless one goes into the rock; and in either the trap, gneiss, or Atlantic formation, the supply is uncertain, erratic, and unreliable, and very rarely successful.

In the post-glacial formation, the drifts fill up the subterranean canals, as they may be called, and the terminal moraine depositions. In this case the water supply is fairly reliable within certain limits. In the speaker's experience there have been two or three curious propositions relating to this question. A certain city put in a water plant in a post-glacial deposition. When the wells were put down they overflowed. Pipes were driven down 80 or 100 ft., and left up in the air 10 or 15 ft., and still the wells overflowed. The pumping plant was started, and, of course, the overflow was gradually lowered. Incidental to that was the fact that, a little above the pumping plant, a man owned a very heavy spring which was totally stopped after a short period of pumping. He brought suit against the company, and, by a curious coincidence, the pumping plant broke down at a certain hour on a certain day, and a certain number of hours afterward, the spring ran afresh. That incident showed the underground capacity of that subterranean gulch, including the capacity of the underground storage.

That formation was almost all sand and gravel. The water-table in 3 years of pumping was lowered from an overflow of 6 or 8 ft. above ground to a ground-water flow of 22 ft. below the surface,

showing that the company was pumping beyond the capacity of the delivery or the water flow of the country. Mr. Owen.

Take the other case, where there is a till flow, that is, in the glacial deposit termed the till, where the percolation is very slow. In certain cases under the speaker's care, the flow of the wells after a rainstorm was carefully timed, and the percolation instead of being immediate, took about 2 days. In the case of one large well, where six or seven holes had been bored into the limestone, and where it was important to have supply enough for the examination, careful note was taken of the times when there was enough water and when the supply was deficient. Examination showed that, after a heavy rainstorm, it took 2 days for this flow through the till, that is, the drift deposit, to get through the rock and into the wells. This shows the extremely slow rate of percolation.

There are a great many interesting questions in the whole region about New York, and it is especially necessary to have known facts tabulated, as there has been a great deal of money wasted, especially in developing what is known as a mysterious underground supply.

In the case previously cited, the wells were put in for the city under the direction of a competent engineer, and the speaker remarked at the time that he was surprised at his being brave enough to put in such a plant for that community. The result has been that that city has been compelled to buy up land and territory after territory to provide a sufficient underground supply.

G. E. P. Smith, M. Am. Soc. C. E. (by letter).—The publication of this scholarly paper on investigations in the Owens Valley, and the studies and conclusions based thereon, must be welcomed by all hydraulic engineers of the arid West. In addition to its immediate or local value, the paper affords a clear and concise exposition of the general principles of ground-water storage, of recharge and loss, and of the extent to which ground-waters can be drawn on for municipal water supplies, irrigation, or other purposes. So far as the writer knows, it is the first comprehensive work of its kind, and the author has the distinction of being a true pioneer of the profession. The paper itself marks a new era in the development of ground-water studies, an era in which scientific basis and logical methods supersede much idle speculation and many misconceptions. Mr. Smith.

Too much credit cannot be given to Mr. Lee for the thoroughness and application of system displayed in his investigations. These features are exemplified in the excellent analyses of rainfall distribution, of seepage losses, and of soil evaporation tests. Where arbitrary factors have been necessitated, they have been based on painstaking inspections and on rare good judgment. In such cases, also, the author was assisted by the extreme uniformity of natural conditions in the Owens Valley, especially of topography, valley fill, soil and

Mr. Smith.

vegetation. The application of system in the investigational work is reflected in its orderly presentation, and in the use of graphical methods, features which add greatly to the value of the paper.

The writer's purpose is not to criticize, but to broaden the foundation on which the deductions and generalizations of the paper are based, and to assist in the extension of their application to a wider range of climatic and geologic conditions.

Beginning in 1906, the Arizona Agricultural Experiment Station has carried on ground-water investigations under the writer's charge in several valleys of southern Arizona. These valleys vary greatly in the degree of aridity, from the grassy sub-arid Sulphur Spring Valley, which is comparable to Owens Valley, to the severely arid Lower Gila Valley. The chief determining factor is the altitude. The ground-water hydrology is exceedingly diverse in character, so that it is difficult to frame generalizations that are applicable to all the valleys.

The most detailed study has been that of the valley of the Rillito,* a tributary of the Santa Cruz, as shown in Fig. 13. There are striking similarities between it and Owens Valley. Both are desert valleys in which the surrounding drainage is toward a broad, flat area, or playa, and therefore they come within the meaning of the term "bolson" or "semi-bolson", as defined by Tolman.† The Pantano watershed spills its surplus water to the Rillito; the Rillito delivers a portion of its drainage to the Santa Cruz, and the Santa Cruz, on rare occasions, has a continuous discharge to the Gila River. Excluding the Pantano bolson with its 620 sq. miles, the total drainage area of the Rillito is 327 sq. miles, of which 56% is mountainous (granitic), 30% consists of dissected gravelly outwash slopes, and 14% is valley land. The area is nearly equal to that of the Independence Region, though the percentage of mountain area is higher. The lengths of the valleys are the same—25 miles—and both derive practically all their drainage from the right-hand side. The mountain rainfall, also, is equal in the two cases, varying from 10 or 12 in. in the foot-hills to 30 or 35 in. at the crests.

The distinctions are: the Rillito Valley lies at an elevation of about 2 400 ft.—considerably lower than Owens Valley—and consequently the temperature is higher and evaporation is greater; the mountainous area drained by the Rillito is on the windward side, and hence the rainfall is comparatively high for the region; the rain-

* *Bulletin* No. 61, Arizona Agricultural Experiment Station, 1910.

† He states: "I therefore suggest that the word be used to cover the watershed of a centripetal drainage system, including all the area within the limits of the divides. The bolson may depart somewhat from a perfect topographical basin, for evaporation on a slope may prevent the development of a through drainage, and foster the centripetal variety. Those bolsons whose surface water in times of flood reaches some river thoroughfare some lower bolson, or the ocean direct, and consequently the playa portion * * * is poorly developed or lacking, may be called semi-bolsons."—*Journal of Geology*, XVII, No. 2, p. 141, February-March, 1909.

Mr. Smith.

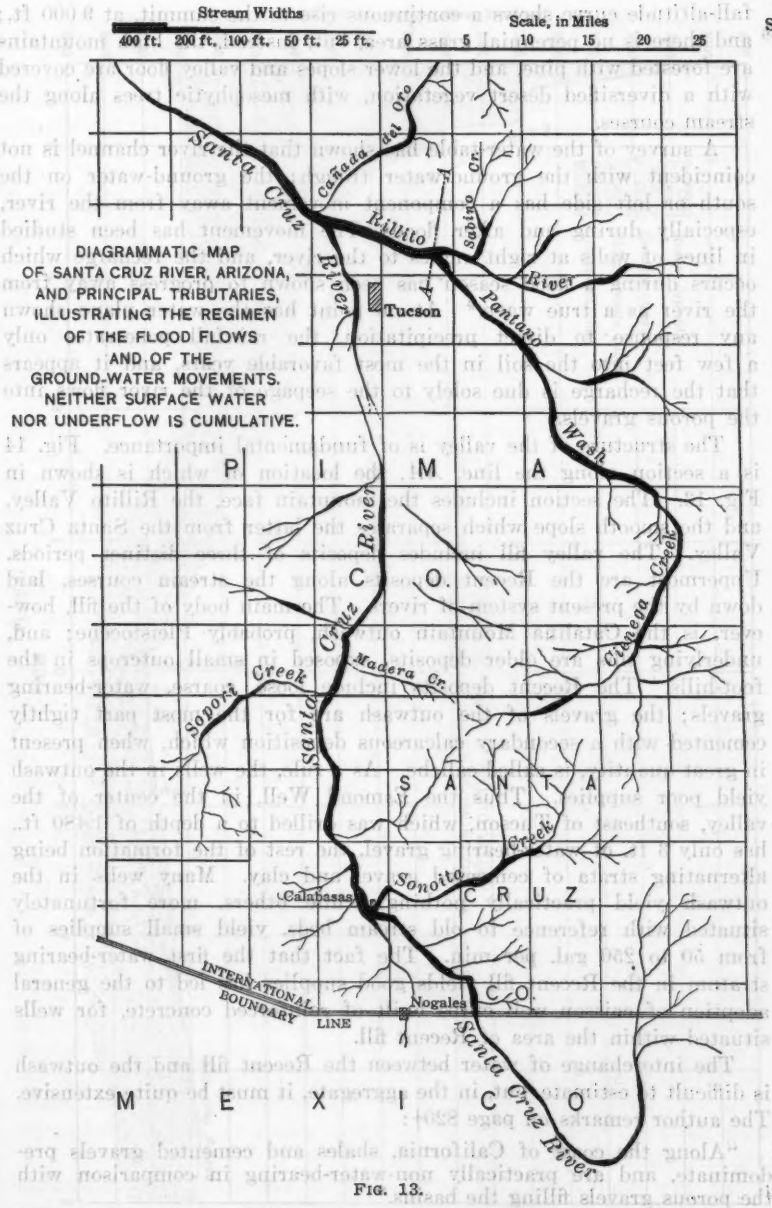

FIG. 13.

Mr. Smith.

fall-altitude curve shows a continuous rise to the summit, at 9 000 ft.; and there is no perennial grass area, but, instead, the high mountains are forested with pine, and the lower slopes and valley floor are covered with a diversified desert vegetation, with mesophytic trees along the stream courses.

A survey of the water-table has shown that the river channel is not coincident with the ground-water trough; the ground-water on the south or left side has a component movement away from the river, especially during and after floods. The movement has been studied in lines of wells at right angles to the river, and the recharge which occurs during a flood season has been shown to progress away from the river as a true wave.* At no point has the water plane shown any response to direct precipitation, the rainfall penetrates only a few feet into the soil in the most favorable years, and it appears that the recharge is due solely to the seepage of the river flows into the porous gravels.

The structure of the valley is of fundamental importance. Fig. 14 is a section along the line, *AA*, the location of which is shown in Fig. 13. The section includes the mountain face, the Rillito Valley, and the smooth slope which separates the latter from the Santa Cruz Valley. The valley fill includes deposits of three distinct periods. Uppermost are the Recent deposits along the stream courses, laid down by the present system of rivers. The main body of the fill, however, is the Catalina Mountain outwash, probably Pleistocene; and, underlying this are older deposits, exposed in small outcrops in the foot-hills. The Recent deposits include loose, coarse, water-bearing gravels; the gravels of the outwash are for the most part tightly cemented with a secondary calcareous deposition which, when present in great quantity, is called caliche. As a rule, the wells in the outwash yield poor supplies. Thus the Esmond Well, in the center of the valley, southeast of Tucson, which was drilled to a depth of 1 480 ft., has only 3 ft. of water-bearing gravel, the rest of the formation being alternating strata of cemented gravel and clay. Many wells in the outwash yield practically nothing, while others, more fortunately situated with reference to old stream beds, yield small supplies of from 50 to 250 gal. per min. The fact that the first water-bearing stratum in the Recent fill yields good supplies has led to the general adoption of caisson well curbs built of reinforced concrete, for wells situated within the area of Recent fill.

The interchange of water between the Recent fill and the outwash is difficult to estimate, but, in the aggregate, it must be quite extensive. The author remarks on page 820†:

"Along the coast of California, shales and cemented gravels predominate, and are practically non-water-bearing in comparison with the porous gravels filling the basins."

* *Bulletin* No. 64, Arizona Agricultural Experiment Station, p. 184.

† *Proceedings*, Am. Soc. C. E., for April, 1914.

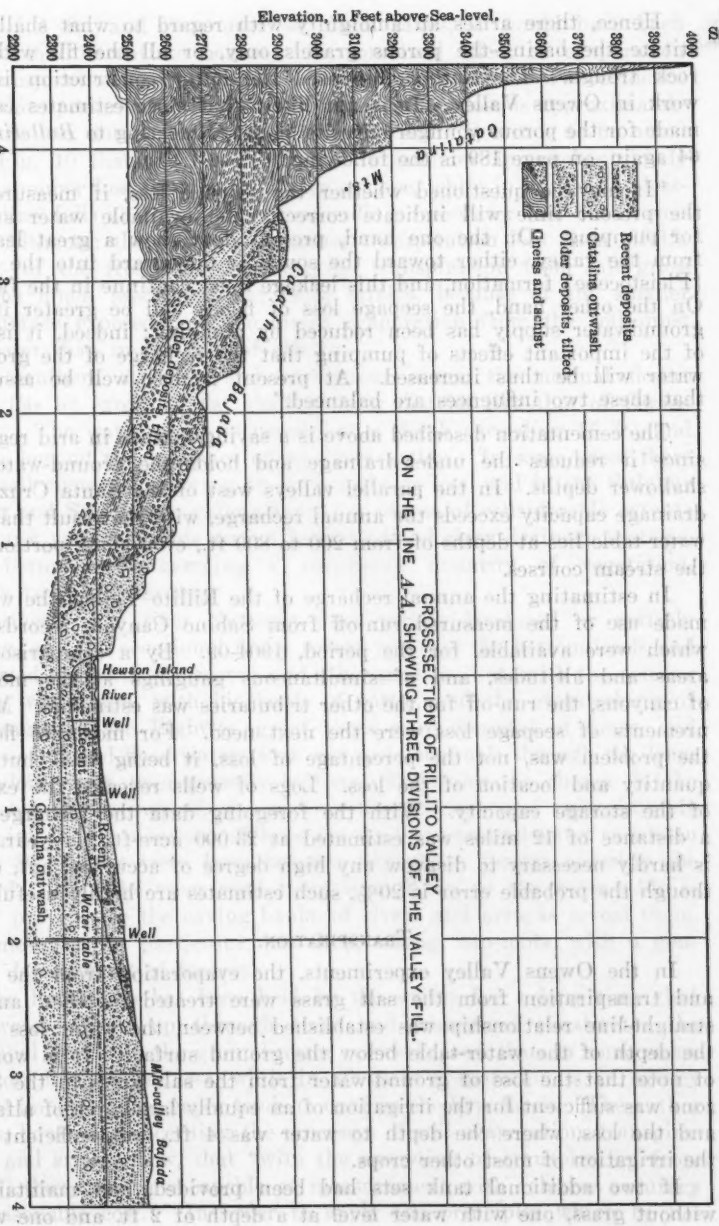

FIG. 14.—CROSS-SECTION OF RILLITO VALLEY ON THE LINE *A-A*, SHOWING THREE DIVISIONS OF THE VALLEY FILL.

Mr. Smith.

Hence, there arises an ambiguity with regard to what shall constitute the basin—the porous gravels only, or all the fill within a rock trough. The author has used the latter construction in his work in Owens Valley. It is not likely that close estimates can be made for the porous younger deposits alone. Referring to *Bulletin* No. 64 again, on page 189 is the following:

"It may be questioned whether the seepage loss, if measured at the present time will indicate correctly the available water supply for pumping. On the one hand, present data show a great leakage from the valley, either toward the south or downward into the older [Pleistocene] formation, and this leakage must continue in the future. On the other hand, the seepage loss of floods will be greater if the groundwater supply has been reduced by pumping; indeed, it is one of the important effects of pumping that the recharge of the groundwater will be thus increased. At present it may well be assumed that these two influences are balanced."

The cementation described above is a saving feature in arid regions, since it reduces the under-drainage and holds the ground-water at shallower depths. In the parallel valleys west of the Santa Cruz, the drainage capacity exceeds the annual recharge, with the result that the water-table lies at depths of from 200 to 800 ft., even along portions of the stream courses.

In estimating the annual recharge of the Rillito Valley, the writer made use of the measured run-off from Sabino Canyon, records for which were available, for the period, 1904-09. By a comparison of areas and altitudes, and of simultaneous gaugings at the mouths of canyons, the run-off for the other tributaries was estimated. Measurements of seepage loss were the next need. For moderate floods, the problem was, not the percentage of loss, it being total, but the quantity and location of the loss. Logs of wells revealed the extent of the storage capacity. With the foregoing data the recharge for a distance of 12 miles was estimated at 23 000 acre-ft. per year. It is hardly necessary to disavow any high degree of accuracy, but, even though the probable error is 20%, such estimates are highly useful.

Transpiration.

In the Owens Valley experiments, the evaporation from the soil and transpiration from the salt grass were treated together, and a straight-line relationship was established between the water loss and the depth of the water-table below the ground surface. It is worthy of note that the loss of ground-water from the salt grass in the 3-ft. zone was sufficient for the irrigation of an equally large area of alfalfa, and the loss, where the depth to water was 4 ft., was sufficient for the irrigation of most other crops.

If two additional tank sets had been provided, and maintained without grass, one with water level at a depth of 2 ft. and one with

depth of 4 ft., and thus used as check tanks, it would have been possible to differentiate between the combined effect of evaporation and transpiration and the effect of evaporation alone. The evidence of the data presented indicates that the combined loss is approximately twice the loss due to evaporation from the soil. For it is to be noted from Fig. 10 that the loss-depth line in summer approaches closely to the summer loss from a free water surface, while in winter the loss-depth line falls short of the corresponding free-water loss about one-half. Although the estimated summer transpiration loss from alfalfa is 87% of the free-water loss, yet the transpiration from salt grass must be much less than that from alfalfa, because of the smaller leaf surface exposed, and the direct evaporation from the soil must be greater than in the case of alfalfa. Mr. Smith.

In southern Arizona and contiguous areas, the normal desert valley has no extensive flat shallow-water district like that of Owens Valley. The water plane is usually at a depth exceeding 15 ft., and is thus beyond the influence of capillary action. In some cases there are small cienegas, covering an acre, more or less, and in the Sulphur Spring and San Simon valleys there are playas of considerable extent; but many valleys of this region have modified river drainage systems, with bottom-lands carrying a surprising quantity of vegetation, usually trees and shrubs.

Formerly, the river channels were poorly developed or entirely lacking, and the occasional floods spread out over the bottom-lands and supported a growth of sacaton and other grasses; but, with the coming of the white man, with his herds of cattle, and the overstocking of the ranges in the Eighties, great areas were denuded of grass, and the concentrated flood-waters soon cut wide channels through the loam and adobe down to a gravelly bottom. Following the change in the character of the run-off, the sacaton disappeared, and trees, notably mesquite, took possession. Where the depth to ground-water is within 25 or 30 ft., the trees have become continuous forests covering the ground. That the trees send their roots down to the water-table is easily proven, for the caving banks of rivers and arroyas reveal them. The mesquite, in particular, has deep, strong, tap-roots, with a generous development of feeders.

The hypothesis has been held by the writer for a long time that the water drawn up through trees and transpired constitutes the principal loss from the ground-water reservoir, and that, in some cases, this loss is the total loss, while in all cases evaporation is an agency of less import. This paper tends to confirm the hypothesis. The author states, however, concerning the processes of soil evaporation, transpiration, and stream flow, that "with the exception of transpiration from trees", they "are now capable of measurement with relative accuracy at reasonable cost." In order to apply the principles which he has

Mr Smith.

so ably developed to the regions somewhat more arid than Owens Valley, it is essential to learn much more than is now known about tree transpiration.

Botanical literature offers little assistance in this problem. The single experiment or estimate which is found in all botanical textbooks is that in Austria a high beechwood forest transpires 30 000 liters daily per hectare during the growing season of 6 months. This is equivalent to 22 in. depth of water over the land. It is stated, further, that from 250 to 500 grammes of water are transpired for every gramme of dry solid matter produced.

Mr. Lee says of transpiration that it "differs in different species of plants," and "King's experiments indicate that humidity does not affect transpiration. For a species growing in a definite locality, light and available soil moisture are the controlling factors." These statements are surely open to question, as will be explained presently. It is probable that all plants tend toward the same rate of relative transpiration per unit of surface exposed, and the principle is well established that humidity is a potent factor of transpiration, as well as are light and soil moisture. The significance of these corrections lies in the fact that ground-water reservoirs are of chief importance in arid regions; and in such regions, with low humidity, brilliant light, and high rates of transpiration, even the xerophytic, or drouth-resistant, plants, under certain conditions, become most profligate in dissipating the only available water resources.

Recent researches of the Desert Botanical Laboratory of the Carnegie Institution have brought out some pertinent new principles of transpiration. The work of F. Shreve in the tropical mountain rain-forest of Jamaica has yielded the conclusions that humidity is a factor of much influence, and that transpiration is approximately proportional to evaporation. He says:*

"Although high humidities (90 to 95 per cent.) have been found to reduce the absolute rate of transpiration below its amount at relatively low humidities (55 to 71 per cent.), as is to be expected, the rate of relative transpiration continued to be of the same general order of magnitude at all humidities which are well above the minimal point for rain-forest plants."

Relative transpiration is a term used to define the ratio of transpiration to evaporation. Further, Shreve has studied data obtained by him in Jamaica in comparison with similar investigations carried on at Tucson, by B. E. Livingston on several desert ephemerals, and by Edith B. Shreve with the palo verde, *Parkinsonia,* which is rated as "a most successful desert tree". To quote again:†

"A general review of the data under comparison indicates that, in spite of minor differences, there is a greater uniformity among

* "Year Book No. 12," Carnegie Institution of Washington, 1913, p. 74.
† *Ibid*, pp. 75-76.

the relative transpiration maxima for the rain-forest and for the desert than might be expected. When such a uniformity is considered in the light of the fact that the evaporation is very many times greater in the Arizona desert than in the Jamaican rain-forest, it forces the conclusion that the transpiration-rates in the plants of the two regions must be roughly proportional to the evaporation-rates, else the relative transpiration-rates would not remain so nearly equal. In short, it is the desert plants in which the rate of transpiration is high and the rain-forest plants in which it is low, which is quite the reverse of the commonly accepted view." Mr. Smith.

G. F. Freeman, plant breeder of the Arizona Agricultural Experiment Station, has made simultaneous tests of transpiration on a peach tree and a creosote bush growing in close proximity. He found a very slightly higher transpiration-rate for the peach tree per pound of green matter, but, when based on the area of leaf surface, the rate for the creosote bush was in excess.* The creosote bush is an extremely xerophytic plant, and forms the principal vegetation of the dryest slopes.

The establishment of the principle of equal relative transpiration-rates makes it possible to eliminate from many discussions factors such as light, air pressure, temperature, and humidity, and to base estimates of transpiration on the more easily measured evaporation from a free water surface. Also, the principle harmonizes the author's estimate of annual transpiration loss from alfalfa with King's estimate for clover in Wisconsin. The leaf characteristics of the two crops are very similar. The estimate for alfalfa is 41 in. depth of water transpired through the plants and 10 in. additional evaporated from the soil; for clover the estimate is 22.3 in. for both processes combined. The rates of evaporation in Owens Valley and in Wisconsin, however, are approximately as 2 to 1.† Since the rates for southern Arizona and for Wisconsin are as $2\frac{1}{2}$ to 1, the inference can be drawn that in Arizona it requires about 56 in. for the proper irrigation of alfalfa.

Before condemning all desert vegetation indiscriminately, however, an ameliorating factor must be taken into consideration. Desert plants possess many queer habits by which they protect themselves from the tendency toward high transpiration-rates. On hot dry days they close their stomatal openings. In times of drouth they drop their leaves. The leaves are invariably small. The leaves of many species are covered with hairs. Some of the cacti are provided with water storage organs either in the roots or in the stems. Hence, plants pass successfully through seasons when the soil moisture around their roots becomes as low as 4 per cent. This power of self-protection is vital to the vegetation of the outwash slopes (usually but improperly called mesas), where the depth to the water level ranges sometimes

* Unpublished work.

† See new Evaporation Chart, "The Plant World," Vol. XIV, No. 9, 1911, p. 219.

Mr. Smith.

as great as 600 ft. There is no evidence, however, that the power is exercised by trees growing on the bottom-lands, where the roots are bountifully supplied from below the ground-water table, or by alfalfa and other field crops, so long as they are well irrigated.

Adopting now the principle that transpiration varies as evaporation, soil moisture conditions being assumed to be uniform, the transpiration-rate for the beechwood forest previously quoted must be multiplied by $2\frac{1}{2}$ to obtain the rate for arid regions. The result is 55 in. depth of water per annum, a quantity that probably represents fairly well the transpiration loss from the cottonwood trees which fringe the rivers for miles and are abundant usually on the upper courses of the tributaries. The loss from mesquite forest, on account of the smaller leaf expanse, is perhaps one-half as great as that from cottonwood trees.

As a corollary to the foregoing discussion, it is clear that the duty of water to be provided for in any locality is proportional to the evaporation-rate. On this basis, the high duty of water maintained in the San Bernardino Valley, in southern California, 7 or 8 acres per miner's inch, is no more creditable than the duty in Salt River Valley, Arizona, where for the last 3 years, the average duty of water, delivered, has been 5.4 acres per miner's inch. Following the over-use of water in many localities where it is abundant, some irrigationists now go to the other extreme, and advocate an impossibly high duty in the most desert valleys. Investigations relating to duty of water should be accompanied always by current observations of the evaporation rate, so that the results, when published, may be of more than local value. This precaution for making the investigations of wide interest has seldom been exercised.

A Principle of Ground-Water Hydrology.

That the ground-waters in arid valleys are not cumulative, is a principle which needs additional emphasis. Although there is a continuous movement of ground-water longitudinally in a valley, yet, in the main, the ground-water of one region does not get down into the next region. In this respect there is a close analogy between surface flows and underflows. Fig. 13 is a diagrammatic map of the Santa Cruz River and its principal tributaries. The widths of the lines are roughly proportional to the widths of the river channels, and indicate the regimen of the floods—the narrow torrents of the mountain canyons, and the spreading out over sandy beds and rapid absorption by percolation after leaving the canyon mouths. Normally, the river beds are dry. Many floods of the headwaters do not reach Calabasas, and few floods which pass Calabasas reach Tucson. The river is ever a dwindling stream, and, though draining greater areas, brings less water and smaller floods to the junctions with some of its tributaries.

Mr. Smith.

than do those tributaries. Finally, at a point about 10 miles beyond the limit of the map, the channel is narrowed down to a width of 12 ft., and 2 miles farther on it entirely fades out. Likewise, the ground-water movements are represented by the same map. These movements are most active where the river beds are widest, where the recharging occurs; but at all points along the stream courses the moving ground-water is sustaining a loss, due mostly to transpiration, and the loss in any region is commensurate to the recharge in that region. The factors of recharge, loss, and forward movement are closely interrelated, though of varying importance in different localities within a region in their effects on the ground-water supply.

A logical sequence of these conditions is that extensive concentrated ground-water development is impossible. Vast areas of fertile land that could be reached easily by canals will ever remain desolate, but there are hundreds of small areas, usually stretching along the river courses, capable of reclamation by the utilization of ground-waters. The best of these small projects are to be found farther up stream. "The mountain water will not come down into the desert very far; we must go toward the mountain. The water must be used as near as possible to its source."*

Another sequence of the foregoing principle is that new diversions of ground-water in arid valleys are not so prejudicial to older rights as has been assumed oftentimes, and the doctrine of priority now applied to underflow streams of a definite character needs modification. In a discussion of the application of the doctrine to underflow gravity ditches,† the writer has suggested four points of limitation. They might well be applied to pumping operations also. The limitations relate to the burden of proof, to the extent of the injury, to co-operation in development work, and to the efficiency of the collecting agencies. Another consideration is that active interference between underflow ditches or between wells does not begin at once, but may require many months of lowering water plane, and, before the time has elapsed, one big flood may refill the gravels, whereupon all effects of the previous drafts on the ground-water supply are obliterated.

Estimates of Safe Yield.

The large items of the author's estimates carry much conviction as to their accuracy. Some of the small items, however, possibly, need additional study.

1.—Percolation from Precipitation on Intermediate Mountain Slopes.—The Sierra slopes are said to be of unfissured granite covered by a mantle of loose rock. Table 16 gives the average annual rainfall as 12 to 20 in., derived mainly from the slow rains and snows of winter. Similar conditions exist on the slopes of the Catalina and

* *Proceedings*, 16th National Irrigation Congress, 1908, p. 206.

† 22d Annual Report, Arizona Agricultural Experiment Station, 1911, p. 570.

Mr. Smith.

Rincon Mountains, near Tucson, but observation indicates that most of the precipitation is absorbed by the porous overburden, wherein it supports an extensive desert vegetation. There is, of course, a slow creeping of the water downward at times, but very little of it reaches the valley. There are springs at the base of the slopes, but they are small, more suitable to be measured in cattle drinks than in second-feet. The run-off factors used for the intermediate mountain slopes of Owens Valley appear to be too high.

2.—The Upper Seeley Spring.—The location of this spring, at the north base of Charlie's Butte, raises a question as to the derivation of its water. If it is lateral flow from the outwash slopes, it is included rightly in the summary of ground-water losses, but if it is river underflow brought to the surface by the intervention of the butte—a hydrologic condition of common occurrence in the Southwest—then it should be omitted from consideration.

3.—It is stated that on the outskirts of the salt grass there is a strip of greasewood and bunch grass, that bordering this there is another zone of luxuriant sagebrush, and that the depth to water beneath these areas is from 8 to 20 ft. In the light of the foregoing discussion on transpiration, it is evident that the water loss from these bordering zones is of so much importance that an effort should be made to measure or estimate it.

4.—Another question of doubt to the writer is whether the underflow at Alabama Hills can be disregarded. The river bottoms here are 3 miles wide, and the rock trough is shown to be at least 832 ft. deep. The slope of the water-table is 8 ft. per mile. Although the valley fill on the Inyo Mountain side is composed of fine sand, yet on the opposite side there may be strata of good water-bearing gravels deposited by living rivers from the Sierra Range. A forward movement of the underflow of 6 in. a day throughout the section implies an item of loss of more than 20 sec-ft. This problem gives the writer more concern because in the arid Arizona valleys the bottom-lands do have usually some good water-bearing gravels. Thus, in the Santa Cruz "narrows", opposite Sentinel Hill, at Tucson, the underflow in the first water stratum must have been at least 10 sec-ft. before the recent development was made. The underflow loss can be measured or estimated by the Slichter method, and should be included in the balance sheet. Perhaps a fair estimate for Owens Valley is that the underflow gain at the north end of the Independence Region equals the underflow loss at the Alabama Hills.

In contrast with the author's orderly estimates are the crude methods which have found favor heretofore. A recent report on ground-water resources in an Arizona valley is based on absurd hypotheses, yet, on account of its authorship, the report ought to have been final and conclusive. The report first recites the water-shed area and rainfall, then applies Newell's run-off curves (which give values

too high for arid regions), then deducts surface run-off, the quantity already applied to irrigation, and an allowance for evaporation from the dry river bed, and asserts that the remainder is underflow at the given cross-section of the valley. It ignores the largest factor of ground-water loss—transpiration—and assumes that the underflow is cumulative from the sources of the stream to the place under consideration. The magnitude of the underflow thus computed is excessively high, and is calculated to invite unwarranted expenditures in development. Mr Smith.

On page 822* is the statement:

"There are * * * two possible methods of measuring the rate of recharge, either by determining the total percolation from various sources into the porous material of the basin, or by determining the ground-water losses."

The latter method is applicable in valleys where the loss areas are fairly compact and the vegetation fairly uniform; but, with a native vegetation of trees and shrubs, diverse in leaf expanse, in height, and in stand, and extending over irregular areas, there is little hope of approximating reliable estimates. On the other hand, as the recharge in very arid valleys is practically all from stream flows, the first method promises more accurate quantitative results. The essential features of the first method are an area survey and some gauging stations carefully selected, at the mouths of representative canyons, at the mouths of representative washes draining the outwash slopes, and near the outlet of the region. Fluctuations in wells, and water contour maps, present excellent qualitative studies, inasmuch as they reveal the direction of ground-water movements, the localities of active recharge, and the areas of loss. The first method has the disadvantage of requiring more attention to the residual losses in determining the safe yield than does the second.

The author has not discussed the probable variations in safe yield from year to year, though this is of great importance. Unfortunately, years of high rainfall, and again lean years, come in long series with great perversity. Rainfall records at Tucson show 6 years, from 1899 to 1904, with less than 10 in. of rain each year, followed by 5 good years with more than 10 in. each year, since which time there have been 4 years with rainfall below the average. The discharge from Sabino Canyon has varied from 2 900 to 46 100 acre-ft. per year. Ground-water levels respond more or less quickly to the variations in rainfall, and in some localities fluctuate over a wide range. Thus, along a section of Pinal Creek, the water-table has been as high as 12 ft. and as low as 85 ft. from the surface. The recent introduction of pump irrigation along the creek will increase the range of fluctuation.

Investigations of safe yield are most fortunate if made during a period when the rainfall is normal. In any case, the investigations

* *Proceedings*, Am. Soc. C. E., for April, 1914.

Mr. Smith.

should extend over several years, so as to eliminate the effects of storage from year to year. If data on the position of the water-table at many places can be secured during the year for which the estimates are made, the increase or decrease in the storage supply can be computed, and should appear as one item in the balance sheet.

Ground-water reservoirs of large capacity are better equalizers of the water supply than are surface reservoirs, but those of small capacity may be poor equalizers. In nearly all cases the highest utilization of ground-water requires the recognition of the principle of fluctuating area under cultivation. Farmers are loath to admit the necessity for fluctuating area, the principle is not ideal, but in time it will be adopted by Courts and otherwise.

The author's summary of residual losses applies to many valleys perfectly. The outlet loss is not a loss to the State, however, inasmuch as it becomes available in the next valley region. What is termed the artesian loss is, in many cases, not truly artesian in character. This loss and the springs' loss are preventable by pumping operations. The loss by transpiration through trees is preventable, also, inasmuch as the feasible pumping lift is much greater than the limit of penetration of tree roots. Developments of the last 3 years in pumping machinery have doubled the economical limit for depth of pumping. Defining the efficiency of ground-water reservoirs as the ratio of the quantity recovered for irrigation to the total recharge, it is fair to anticipate, and to design works for, an exceedingly high efficiency, higher than many surface reservoirs, which lose from 3 to 10% through evaporation and an equal quantity through losses from a long supply canal.

Methods of increasing the safe yield require some variation from those proposed, in order to make them applicable to conditions in very arid valleys. Efforts to bring about greater absorption of flood-waters are not needed. The floods are wholly absorbed now, except for an occasional season of high rainfall, occurring perhaps once in 15 years. The efficiency of absorption through stream beds must be higher than that of absorption on an exposed slope. The only promising method is the elimination of transpiration through the denudation of the bottom-lands. The native forests and scattered trees should be removed, and, so far as the water supply permits, replaced by vegetation that is useful to man.

In conclusion, the investigations in Owens Valley are timely, for the extensive development of ground-waters in the Southwest points already to the over-draft, and in some places to the exhaustion, of the supply within a few years. The Engineering Profession, and not the Courts of Law, should take the prominent part in the final adjustment of pumping operations to the limiting physical conditions.

CINDER CONCRETE FLOORS.

Discussion.*

By Messrs. A. W. Buel, Charles C. Hurlbut, W. B. Claflin, F. W. Skinner, Oscar Lowinson, George E. Strehan, and A. L. A. Himmelwright.

Mr. Buel.

A. W. Buel, M. Am. Soc. C. E.—When safe working stresses for cinder concrete have been correctly determined for various specified conditions encountered in practice, it will without much doubt become clearly apparent that there is little, if any, economy in its use for structural elements subject to stress, notwithstanding its lower weight per unit of volume as compared with stone concrete.

The speaker regrets that the author has not taken up the question of the corrosion of embedded steel, as it is of vital importance in a permanent structure, especially as the records of some experiments and considerable experience have shown bad results.

Although a satisfactory series of experiments from which to deduce safe unit stresses for cinder concrete would be a valuable addition to our knowledge of the subject, it would seem advisable first to determine by experiment and experience whether the material is suitable for permanent structures, and that the reinforcing metal is reasonably safe from corrosion. Until this is done, it will hardly be safe to specify cinder concrete for reinforced members or to adopt it as an acceptable material of engineering or of construction—except as a filler—no matter how satisfactory the experimental determinations of its strength may be. In other words, it seems to the speaker that the first experimental and research work with reinforced cinder concrete should be confined to the question of the corrosion of the reinforcing metal, and unless the results are satisfactory on this point it would be a waste of time and money to enter on elaborate experiments to determine proper unit stresses.

* Continued from May, 1914, *Proceedings*.

Mr. Buel. It has been suggested that corrosion sometimes takes place with steel embedded in stone concrete. This is quite true, but as far as the speaker has been able to ascertain corrosion of reinforcing metal in good stone concrete is almost invariably due to one of two causes: electrolysis or palpable defects in design or construction, for both of which there are practical protective measures affording reasonable security. Certainly, one can hardly hope for absolute security, but there is evidence that iron embedded in stone concrete has been preserved rust free for periods as great as 400 years.

The following notes relate to the corrosion of reinforcing metal embedded in cinder concrete: Mr. William H. Fox* states that the results of experience and experiment show serious corrosion in almost all cases, and recommends that with cinder concrete no mixture less rich than 1:1:3, or one still richer in cement, should be used. In a report of a committee read before the Structural Association of San Francisco, it was stated that metal encased in cinder concrete had been corroded, and the committee advised a revision of the code, to exclude the use of cinder concrete. Mr. Fox reports a set of experiments at the Thayer School, with the following conclusion:

"With but one exception, one or more of the three steel pieces in each specimen showed unmistakable signs of corrosion. Apparently it made no difference how the concrete was mixed—wet or dry, tamped or untamped; whether the steam or water treatment was used, the result was the same—rust streaks and spots were found, the difference in the amount of corrosion being imperceptible."

These records seem to make a case against cinders for reinforced concrete that will require something more than explanation, and a good deal of substantial evidence to the contrary, before conservative engineers and architects can safely adopt this material. The advocates of cinder concrete should accept the task of making the necessary demonstrations.

Mr. Hurlbut. CHARLES C. HURLBUT, ASSOC. M. AM. SOC. C. E.—This paper takes a long step toward putting cinder concrete on a rational basis, like other materials of engineering. That it is a perfectly reliable material for many purposes, when made with a good grade of cinders, the speaker is convinced from his own experience. It is not suitable for any work requiring density, such as foundations or outer walls, neither is it suitable for reinforced beams and girders where a stronger material is required; but for floor-slabs between steel beams, as in modern skeleton construction, with relatively short spans and moderate loads, it is very satisfactory. It is not because a great deal of cheap and shoddy work has been done with it, but in spite of that fact, that 90% of the fire-proof floor construction in New York is of cinder concrete. The speaker has repeatedly seen new cinder concrete

* *Engineering News*, May 23d, 1907.

floors in buildings under construction carry loads enormously in excess of those for which they were designed or would ever be called on to carry in actual use. Any one having much experience with cinder concrete in floor-slabs is sure to acquire considerable respect for its load-bearing qualities. Of course, a slab of stone concrete of the same thickness is much stronger, but if the slab is stronger than necessary, there is obviously no gain in increasing the strength, and usually it would not be advisable to decrease the thickness much, even if stone were used. Mr. Hurlbut.

On the other hand, there is no doubt that there has been a large quantity of very inferior cinder concrete work. Sometimes, this is the result of direct "skinning" of the mix, and sometimes it is due to the use of unsuitable cinders. Good cinders are sometimes hard to obtain, even with the best intentions, and on many occasions, the speaker has rejected cinders on the job, which otherwise would have been used in the floor construction. It may be noted in passing that the floor construction in question had been duly "passed" by the Building Department, but it is safe to say that the test on which the approval was based was made with very different cinders from those rejected, illustrating Mr. Waite's objection that the Building Department tests have small relation to what may be expected of any particular floor. The cinders rejected were, in some cases, full of unburned coal and, in other cases, little but fine ashes. Wherever cinders are used, they should be subject to rigid inspection. In the matter of unburned coal in cinders, although it is the speaker's practice not to accept cinders containing more than the small necessary proportion, it is his opinion that the danger from unburned coal in concrete is over-estimated. This opinion is based on a rather crude test made on a partition built of 2-in. cinder concrete blocks. The blocks were literally filled with unburned coal. A small covered enclosure was built and subjected for more than an hour to a very hot wood fire. The coal on the surface was reduced to cinder, but all below the surface seemed to be entirely unaffected.

The objection has been raised, in designing cinder concrete by formula instead of by test, that the material is too variable. This argument does not seem to be well founded. Given a certain system of reinforcement, the strength of any floor-slab will vary from that developed by a full-sized test sample in just the same degree that the materials in it vary from those in the slab tested. It is just as proper, therefore, to designate a safe unit compressive strength and other properties for cinder concrete as it is to assume a safe slab strength based on a test, and far more rational. As a matter of fact, it is a far safer method, for the average strength of cinder concrete can be determined with some approximation to the truth by taking a large number of tests on varying grades of cinders. On the other hand, a

Mr. Hurlbut.

test made on a slab proves little beyond the slab tested. Only one test is made on each "system", and it is safe to say that the cinders entering into these tests are the best that can be obtained. The speaker has witnessed a number of these tests; he has seen some of the test slabs built, and knows that the cinders were better than the average used throughout the city. The charge is not made that any of the tests have been "faked", or even that the materials used were not such as can be obtained in the open market, but merely that the tests of which the speaker has knowledge were made with rather exceptionally clean cinders, which are not always used in actual construction. No proof as to the accuracy of an engineering formula would be deemed conclusive if based on a single test, and yet a single test with an admittedly variable material is here used as a pattern to be followed without variation. It would be possible to define a standard cinder aggregate, the properties of which would not vary beyond reasonable limits, no more, for instance, than timber varies, or some other materials the use of which is based on rational formulas. The proportion of fine ash can readily be determined with a sieve of some standard mesh, and the percentage of unburned material can be determined with sufficient accuracy by means available almost anywhere. These are the two principal uncertain and variable elements in cinder as used in concrete.

A serious objection that has been raised to the use of cinders is their alleged tendency to corrode metal with which they come in contact, and it is to be regretted that the author did not take up this phase of the question. It has been the speaker's opinion that a cinder concrete, if mixed not leaner than 1:2½:5 and placed rather wet, would not injure pipes or steel reinforcement embedded in it. No cases of corrosion clearly attributable to the cinders have come to his attention under these conditions. There are many cases, however, where pipes, embedded in weak cinder fill, have been destroyed, and the presumption has been that the cinders were to blame. It is the speaker's practice to specify and enforce rigidly the requirement that all pipes embedded in the floor construction or fill, where cinders are involved, are to be solidly encased in cement mortar made with 1 part of cement to 2 parts of sand. The Lackawanna Railroad has experienced considerable difficulty with the corrosion of pipes in its stations which, in some cases at least, the engineers have attributed to the effects of contact with cinder concrete. Owing to this belief, they are now prohibiting cinder concrete in every form. In this case, at least some of the trouble was subsequently found to be the result of electrolysis. How much of the corrosion, if any, was actually due to cinders, it would be hard to say. It is quite possible that in other cases of damage to pipes, cinder concrete has been made to bear the blame which should have been attributed to stray currents of electricity.

W. B. CLAFLIN, M. AM. SOC. C. E.—The use of reinforced cinder concrete for floor-slabs and as a fire resistant has reached such proportions, especially in Eastern cities, that its importance as a structural material should be brought to the attention of the Profession at large, and Mr. Waite's paper will be instrumental in accomplishing this. Mr. Claflin.

Some time prior to the introduction of cinder concrete in New York City, architects had become more or less dissatisfied with the materials and methods of fire-proofing then in common use. They were either cumbersome and heavy, or proved inefficient when subjected to great heat. The economic conditions which caused the development of tall buildings and the necessity for reducing the dead loads for the purpose of eliminating the excess of steel in the frames, made it desirable to obtain a material that was durable, fire-resisting, and light. About 16 or 17 years ago, cinder concrete, having been officially tested and approved by the New York Building Department, was introduced. That it has been a success in its limited field of application, time has shown conclusively. The method of testing originally devised, and still followed, does not give accurate results, but was the best that knowledge then available afforded.

For several years after its introduction, the cinder concrete industry was dominated by reputable individuals and companies of financial responsibility who generally controlled a patented method of reinforcing which was not available to others in the trade. It was their custom, as a rule, to arrange for a steady supply of cinders from fairly reliable sources.

The patents referred to cover the forms of reinforcing bars and rods, either plain or deformed, with spacers, clips, and hangers for insuring the proper placing of the reinforcement and holding the concrete protecting the bottom flanges of the steel floor-beams and girders. There is also a rectangular wire mesh with welded intersections, which is one of the best types of reinforcement.

Each concern conducted a series of tests under the direction of the Building Department, and obtained approvals on forms of construction which gave the architects a range of choice sufficiently wide to cover generally all the requirements of practice. The conditions in the trade were fairly stable, with reasonable competition, a good grade of cinders, and responsible concerns to deal with.

Five or six years ago a subsidiary of the Steel Corporation began the manufacture of a triangular-mesh, wire reinforcement, which, having been tested and approved in slabs of various spans and for various quantities of steel, was placed on the market. This is sold to any one having the means to pay for it, and is so cheap that, in many instances, as a result of the ensuing sharp competition, the proprietors are obliged to use it instead of their own methods of rein-

Mr. Claflin.

forcement. No criticism of this form of reinforcement is here implied, for it is one of the best in use to-day.

The trade is not now in such a satisfactory condition as formerly, for the reason that an irresponsible, unskilled, and, too frequently, careless element has appeared, which, through ignorance or willingness to assume risks, underbids its more conservative and responsible competitors. It is practically impossible for the architect to induce the average owner (especially the speculator) to discriminate between the two elements in the trade. Cinder concrete is cinder concrete to him, and it is difficult for him to see beyond the dollars apparently saved by the acceptance of an unduly low estimate.

In times of normal building activity, it is difficult and sometimes impossible for the new element in the trade to obtain cinders of good quality; consequently, they are often taken from household refuse at the dumps, and contain all sorts of foreign matter adversely affecting their quality and the strength of the concrete.

The foregoing has been written for the purpose of showing clearly the influences which have resulted in conditions as they are to-day.

For some time the method of arbitrary tests imposed by the Bureau of Buildings has caused dissatisfaction, not only in the trade, but among architects, because they require much time and are expensive, and because the approval is limited to the exact form tested, no variation whatever being allowed. This means that a firm desiring to use a number of forms of construction must take the time for, and incur the expense of, a test on each one, no matter how slight the difference may be.

This condition has naturally led to the desire, on the part of the cinder concrete interests, for a more rational and simple method of determining the strength of slabs, and the proposal to calculate their stability on the basis of unit stresses is the result. This proposal is logical and highly desirable, if it can be done with safety, but there are points involved which would seem to make it unwise.

Until recently all slabs were tested under uniformly distributed loads, developing unbelievable carrying capacities. The only way to account for this is that the load arches itself, a large and indeterminate portion being transferred to the haunches. Reference to Fig. 2* will show at a glance that arching occurs. In fact, it would require great skill in placing the load to prevent it. We are in the dark, therefore, as to the true strength of the slabs we have used. Within the last two or three years slabs have been tested under concentrated loads at the middle.

As has been intimated, it is difficult to obtain cinders of anywhere near a standard quality. In one building, where the cinder concrete would not set, investigation showed that, although apparently clean,

* *Proceedings*, Am. Soc. C. E., for April, 1914.

on being wet, strong fumes of ammonia gas were liberated. Further inquiry showed that the cinders had come from a brewery in which one of the ammonia pipes had burst over the place where they were stored. In another case, it was found that the cinders (in some concrete which would not set) had come from a sugar refinery and were impregnated with molasses. Fortunately, the work was being done by reputable concerns, and the faulty cinders and concrete were removed, care being taken to have them clean thereafter. Mr. Claflin.

Portland cement is now a standard material, and can hardly be considered an element of uncertainty except in cases where it is not properly protected prior to use, or is mixed in improper proportions. This may be generally applied to the sand used in the city.

The proper inspection of cinder concrete requires a superintendent continually on the work to see that the materials are of the proper kind, and that they are mixed and placed as they should be. It is practically impossible to persuade an owner to incur the expense of a clerk of the works, especially in commercial work. This is another valid reason for a strict law safe-guarding the use of cinders.

The most uncertain of all the elements entering into the composition of any concrete, but more especially cinder concrete, is the so-called human element. Carelessness in or indifference to any one of the many precautions which must be observed in the mixing and placing of concrete may lead to failure.

If unit stresses are used in the calculation of cinder concrete slabs, they should be low enough to discount faulty cinders, carelessness, possible dishonesty, indifference, and lack of inspection. To accomplish this, the unit stresses must be so low that the cinder concrete interests themselves would object on the ground that the quantity of material required would be increased to such an extent that they could not compete successfully with other forms of floor construction. If unit stresses are used, the cinders should be standardized; the law should require that they be washed and screened.

The fire-resisting qualities of cinder concrete have been developed so many times in tests and during actual fires that it would seem that the time has come when they may be accepted as proved and fire tests eliminated in the future.

Recommendations.—The speaker makes the following recommendations:

1. That the Bureau of Buildings conduct a series of tests, approximating as closely as possible commercial conditions in the mixing and placing.

2. That the slabs be tested under concentrated loads at the middle of the spans, with various combinations of span lengths, thicknesses of slab, and areas of reinforcement.

Mr. Claflin.

3. That the results of these tests be divided by a conservative factor of safety and the remainders be tabulated for use as the basis of slab design. For instance, if it is desired to use a slab 4 in. thick, with a 6-ft. span, carrying an applied load of 150 lb. per sq. ft., a given area of reinforcing steel per foot of width should be required.

4. That a ruling be made requiring the washing and screening of all cinders used in all future buildings.

5. That all existing approvals be revoked, after the results of the new tests are available.

The adoption of these recommendations would place the use of cinder concrete on a rational basis and enable those interested to proportion the slabs with a degree of freedom and safety hitherto unknown.

The corrosion of steel embedded in cinder concrete has been mentioned. Several years ago A. N. Talbot, M. Am. Soc. C. E., embedded steel in cinder concrete and concluded that the corrosion was negligible, because, with the wet mixtures used, a film of cement was deposited around the steel which protected it against the action of any chemicals in the cinders tending to cause corrosion.

It is not safe to place unprotected pipes in the cinder fill over slabs. This can probably be explained by the fact that the mixture is usually 1:7 or more, and is placed quite dry, the consequence being that there is not sufficient water present to carry in suspension enough cement to coat the pipes. Piping thus placed should always be given a heavy coat of asphaltic or similar acid-resisting paint.

About the only knowledge we have of the effect of cinder concrete on reinforcing steel in actual construction is derived from the Pabst Building, which was removed (to make way for the Times Building) after having been occupied for 7 years. Corrosion of the steel was found in a few places, but not to a degree affecting its strength. Pipes embedded in the cinder fill were badly corroded.

Mr. Skinner.

F. W. Skinner, M. Am. Soc. C. E.—The speaker's recollection is that, when cinder concrete was first used, it was very largely promoted and intended chiefly as a filler, a light cushion, or a cover for other construction, and it was not expected that it should be subjected to very heavy stresses or that great responsibility should be placed on it. It was found to be convenient, light, and cheap, but it has had larger and larger duties placed on it ever since.

As regards construction, however, concrete of the best quality is one of the most important engineering materials, and one which probably more than any other, varies and is subject to very great modifications through its components and through the manner of its manipulations; it cannot be made and inspected too carefully. Stone concrete without reinforcement is very different from cinder concrete, which is lighter and of more uncertain proportions, and is, and should be, chiefly adopted for mass and fill and for reduction of weight.

Mr. Skinner.

It seems to the speaker that any discussion which gives cinder concrete equal technical weight with a carefully prepared stone concrete, which can be subjected to thorough tests and be made a permanent material of construction, is hardly fair. It is carrying the question beyond the limit of technical considerations, even though it is not beyond the manner in which it is used. In this discussion the most important consideration in regard to cinder concrete is whether it is used to-day in the proper manner and for the proper purposes.

Mr. Lowinson.

OSCAR LOWINSON, ASSOC. M. AM. SOC. C. E.—As an authority on building codes and also on the fire-proofing of buildings, Mr. Waite has no superior. His experience in concrete construction and in the formulation of requirements in building-code matters, is such that his argument—that definite standards for reinforced cinder concrete construction should be established on a mathematical or scientific basis, rather than as a result of tests—entitles him to a respectful hearing.

One great problem in New York City, however, has been to try to make laws which will meet the conditions in the trade; and though this discussion as to the strength of a cinder concrete arch is all right when one knows what material enters into the structure, the trouble has been that frequently the material used is not cinder concrete as an engineer understands the term.

This unfortunate condition of affairs has arisen from the fact that the majority of the concerns who are engaged in cinder concrete construction are utterly irresponsible, have no engineers in their employ, and are subject to no supervision other than that casually given by the building inspector, who usually has only a few moments in the day to devote to the building. Consequently, those familiar with the conditions marvel at the few accidents that occur in New York City, for it is well known that, if it were possible to determine thoroughly the strains in the material which is called concrete, in a large number of cases, it would be found to be strained far beyond the breaking value due solely to the utter disregard of the requirements for reinforced cinder concrete construction.

The expedient was adopted of having tests and giving permits for each type of construction, and for a while this method was effective in that it compelled the installation to correspond to an approved test. Later, however, it was found that the concerns who complied with the tests could no longer compete in construction with the contractors who were willing to install, and the work has gradually drifted so that the concerns who make the tests, to-day, only sell the reinforcement, and the construction is done by other parties.

Under such conditions it is impossible to adopt any kind of a standard, either so-called scientific or practical, of any value; and it is doubtful whether it would be an improvement to change the method of requiring a standard. This certainly is a hardship to a conscien-

Mr. Lowinson.

tious contractor. It is only one of the unfortunate things in the building trade.

This subject is not new, as discussion on the formulation of data with reference to reinforcement has been going on since 1907. New York City has had five proposed building codes, and another is now under way. It is hoped that a building code will be established which will eliminate standards of this type entirely, leaving their determination to the formulation of regulations by the authorities. Possibly, by such a method, a building code may be adopted, which will be based, more or less, on rational ideas.

Heretofore, the difficulty has been the utter irresponsibility of those who are putting in the material and the lack of inspection of the material going into the structure. As a result of this experience it was determined years ago, as Mr. Waite has stated, that it was better to depend on tests with a material of this sort, and establish standards from the basis of such tests, than to attempt to establish standards or unit stresses in a combination material, like reinforced cinder concrete, and the authorities have been very slow in showing any sympathy with the idea that they can establish standards with reference to this mixture.

With a stone mixture one can establish a standard and can generally feel satisfied that the results will be fairly in accord with it. The aggregate is dense, and there is no possibility that it will disintegrate if the slightest inspection is undertaken. With cinders, however, one does not know what to expect; and it is on that account, more than anything else, that the standards in the code of 1912 were established after considerable discussion as to whether or not unit stresses should be permitted in the reinforcement of cinder concrete, and it would have been possible under a similar code, revised as a result of the discussion that took place after the publication of the original code, to establish certain standards of material made on a basis more or less scientific.

The speaker does not think it advisable to establish standards of that sort in any form, other than with reference to the thickness of the material and the quantity of reinforcement per unit or per square foot, by establishing a minimum, because of the fact that with such materials and with mechanics of the type engaged in that work in New York City, to-day, it is not advisable to go further.

With reference to the corrosion of pipes when buried in concrete, experience has taught us that the only way to feel sure that pipes will last is to insulate them, and thereby prevent the corrosion from getting at them. A wrought-iron steam pipe, embedded in a concrete floor, is good for from 2 to 5 years. It is the custom, especially in cellars, to try to keep the return pipe above the floor level. Corrosion in pipes is practically due to oxidation, caused by the sulphur in

the cinders, or by the porosity of the concrete permitting the moisture, which is alkaline, to attack the pipe. Mr. Lowinson.

There has been a great deal of trouble with hot-water supply pipes, when buried; they corrode more rapidly than the cold-water pipes. Frequently, over these pipes there is a layer of plaster of Paris, or cement from a tile floor, and the corrosion is generally attributed to the above-mentioned cause, to which is added expansion and contraction of the pipe caused by variations in temperature.

It has been found that corrosion occurs on the outside and also on the inside of the pipe. Chemists may be able to explain why the corrosion takes place on the inside as well as on the outside, and why it is more active in hot-water than in cold-water pipes.

GEORGE E. STREHAN, JUN. AM. SOC. C. E. (by letter).—The author's object in recommending that the application of cinder concrete in fire-proof floor construction be placed on a so-called scientific basis is to be commended. However, the writer fails to find any plausible basis in the paper on which to establish constants for calculation and unit stresses for design. The author states that there are sufficient precedents for establishing such factors, but a careful perusal of the paper does not elicit much information of great value along this line. Table 3, showing the physical and elastic characteristics of cinder concrete, which the author presents, was taken from a preliminary report of an investigation being made at Columbia University, and these data in themselves are not sufficiently comprehensive to be used as a basis for design. Mr. Strehan.

Cinder concrete, as applied in New York City and vicinity in fire-proof floor filling between steel beams, is a material with which the author should be thoroughly familiar from long years of experience, both as a contractor and as an "expert tester." The knowledge thus gained should have convinced him that such a floor, built between rigid I-beam supports on ordinary spans of from 6 to 8 ft., is an entirely different structure from reinforced concrete of the slab, beam, and girder type. On spans up to 8 ft., and with a thickness of not less than one-twentieth of the slab length, the writer's investigations have shown that such factors as arch action, tension in the concrete, and the trussing effect of continuous reinforcement, all of which the author neglects, are important features in floor construction of this type.

The author ridicules the term "continuity" thus used without apparently realizing that it is not the continuity of the concrete slab which is referred to, but the anchoring of the reinforcement over the steel beam, and although he has little faith in it, he still feels that such continuity obtaining in the test construction and not in actual buildings has resulted in the excessive load approvals. Based on both theory and test, it can be shown that this strength, of the worst condition that occurs in building construction, that is, the

Mr. Strehan.

end slab adjoining an open bay or exterior wall, is about three-fifths of that of the test construction as ordinarily installed. The author failed to note that the tests conducted by the Bureau of Buildings, with the resulting approvals to which he refers, were made on the basis of a factor of safety of 10. This, in the end-panel condition of actual practice, would correspond to a factor of safety of 6 for the approved loads.

The writer does not undertake to defend the method of handling cinder concrete floor construction which obtains in New York City, but believes that a rational basis for design should be established. With this end in view, a paper is now in course of preparation which it is hoped will soon be ready for publication. The investigation has included a study of the preparation of the raw materials, with the object of improving the mixture. Very little, if any, benefit has been derived by screening the cinders; in fact, the resulting concrete has shown a decrease in strength when compared with the ordinary 1:2:5 mixture in which hard coal cinders, as received from the boiler, are used.

The author states that the form of reinforcement is immaterial. Exception must be taken to this statement, because, in some tests of slabs reinforced with plain and deformed rods, the plain squares and rounds failed by the slipping of the reinforcement. The question of adhesion must undoubtedly be taken into account in the design. The writer wishes to emphasize further the fact that if the reinforcement is anchored to the steel girders, the resulting construction differs radically from the type of slab, simply reinforced, on which the author bases his plea for design. The extension of cinder concrete to general application in slabs, beams, and girders should in no case be recommended, in view of the variableness of the material. Its use between steel beams as a special application has undoubtedly proved satisfactory; but, even in this case, there should be greater caution than is now generally shown in the selection and preparation of the raw materials for the concrete.

Mr. Himmelwright.

A. L. A. HIMMELWRIGHT, M. AM. SOC. C. E. (by letter).—The subject of cinder concrete floors is one in which the writer is greatly interested. The idea of rationalizing the theory and practice of their construction is not new, and would be most desirable if a practical and correct formula could be evolved that would be generally applicable to the different forms of reinforcement and methods of using it. The writer spent much time years ago in attempting to develop such a formula, and was obliged to give up the attempt.

Mr. Waite's arguments are relevant, but, unfortunately, they are applicable only to the ordinary and usual types and methods of reinforcement, and would not include numerous others equally desirable.

Mr. Himmelwright.

Take, for example, an abnormal case, such as a reinforcing metal without rigid intersections, of which hexagonal mesh netting is an extreme case. In this netting the metal does not actually get into tension until the concrete slab cracks and fails, when it acts as a suspender. This material, of course, is unsuitable for the purpose of reinforcement, but it illustrates a type, such as "crimped" reinforcement, which is actually sometimes used. Then, again, there are forms of bar reinforcement, such as what is known as the Roebling System B, with 2 by $\frac{3}{16}$-in. flat bars set on edge. The reinforcing bars in that position in the slab have considerable value as beams, and the actual strength cannot be even approximated to by any formula that gives fair results with a bar of square or round section.

This type of construction is one of the most fire-resisting flat-slab methods now in use, because the bars, extending deep into the concrete, are protected by it, and in that position do not become heated as quickly as when the center of section of the reinforcing metal is nearer the under surface. When any of the ordinary formulas are applied to this type of flooring, they scarcely give it strength enough to support its own weight, whereas actual tests have shown its strength to equal, and in some cases exceed, that of the average of equivalent square and round bar reinforcement used in the ordinary manner.

The great difficulty in evolving a rational theory of design is that the strength is not the only important feature of fire-proof construction; fire resistance and durability are even more important. Conditions which will produce the greatest strength generally result in the poorest fire resistance; that is to say, the farther away the reinforcing metal is from the neutral axis and the nearer it approaches the underside of the slab, the greater will be the strength; on the other hand, the nearer the reinforcing metal approaches the under side of the slab, the thinner will be the protective covering and the more quickly the reinforcing metal will be heated in a fire so as to become weak.

The question of durability is most important. Exposure to the elements, which is a necessary condition in practical building construction, always causes initial rusting. When the reinforcing metal is in the form of bars or rods of considerable size and section, the rusting is not important, and does not materially weaken the metal. When, however, the reinforcement is in the form of wire or small mesh made from light sheet-metal or similar material, the rusting affects the strength very materially by reducing the effective section, and when embedded in wet concrete it continues to rust in rainy weather and until the building is roofed over. In extreme cases such reinforcing metal under normal conditions becomes weakened by oxidation, so that it retains only a fraction of the strength shown by the formula.

Mr. Himmelwright.

Density is another factor that has large importance in cinder concrete fire-proofing. When stone aggregates are used and the concrete is thoroughly rammed so as to eliminate all voids, the action of the concrete approaches more nearly to that of the solid stone of which the aggregates are composed, and it cracks much more readily when exposed to heat and sudden cooling than when the concrete is full of voids. This, in fact, is the principal reason that cinder concrete develops higher fire resistance than any concrete with stone aggregates. It is impossible to eliminate all the voids in the cinder aggregate by ramming, as such voids are always present in the aggregates themselves, to a greater or less extent, even if the cementing material is free from them.

Tests made by the writer conclusively demonstrated that the more porous the concrete the less likely it is to crack and fail under sudden and violent changes of temperature. Cinders crushed so as to pass a ¾-in. screen, made into concrete mixed in the proportion of 1 : 2 : 5, and simply spread over the forms and leveled and patted down with shovels in segmental arch construction, will develop ample strength to carry ordinary loads up to, say, 200 lb., with a safety factor of 5. The material manipulated in this way will be extremely porous, light in weight, and exceed in fire resistance any other material known to the writer, except possibly a concrete made from "tetzlonti," a porous lava rock which the writer has used in a number of buildings in the City of Mexico.

It is well known, of course, that density is desirable, as tending to prevent oxidation of the steel reinforcement, as oxidation takes place more rapidly where voids occur in the surrounding concrete; but this oxidation practically ceases when the concrete becomes perfectly dry after a building is enclosed and finished. This phase of the problem, therefore, is of minor importance, especially when the reinforcing metal is in the preferred form of rods or bars of considerable section.

The economic advantage of voids in securing lightness is much more important than the initial oxidation, but it has never received the attention it deserves. A concrete made and deposited as above described will weigh only from 70 to 75 lb. per cu. ft., as against 95 to 100 lb. when thoroughly rammed. This is a gain of 25% in the dead load, in favor of economy, and, as above stated, ample strength is also obtained.

From what precedes it will be apparent that certain qualities and conditions which result in improved fire resistance, both in the form of the reinforcing metal and in the concrete, tend toward weakness, so that we have two conflicting elements in the design of cinder concrete floors which will forever prohibit the development of a practical rational formula of general application.

Mr. Himmelwright.

An important feature of this whole problem is the fact that it is a mistake to legislate or inaugurate regulations that are restrictive and tend toward the development and improvement of only a few forms of construction. The error of this, perhaps, is more plainly illustrated in the regulations governing theater construction than in anything else. All the building laws at the present time specify refinements of the conventional design for theaters, and absolutely prohibit other designs which might provide greater safety and result in larger seating capacity. It is always better, in preparing building codes and city ordinances, to specify results to be obtained rather than detailed specifications.

Although strength in cinder concrete floors is a most desirable feature, others, equally desirable, should not be needlessly sacrificed and discouraged by ill-advised regulations. To make all forms of construction comply with a rational theory would immediately eliminate some of the best methods, as it would be obviously impossible, with the same materials and at the same cost, to develop a superior fire-resisting construction which would show by formula a strength equal to the ordinary method with the reinforcing metal as near to the under side of the slab as the law would permit.

The writer is disappointed that more progress has not been made in the direction of economy and in improving the fire resistance of cinder concrete floors. Practically all the progress during the last 5 years has been in the direction of securing the maximum strength with any given reinforcement; the protection of the latter being controlled by building codes and regulations, the thickness of the concrete protection varying from $\frac{1}{2}$ to $1\frac{1}{4}$ in. in different cities. The general tendency in this one direction of securing strength, which is largely the result of existing restrictive codes, has no doubt discouraged and minimized improvements in other directions, and has accentuated the supposed desirability of rationalizing all forms of cinder concrete construction.

The best that can be done with the problem is to develop a theory and formula in accordance with the results of the usual and more common forms of cinder concrete floors, as proposed by Mr. Waite, and, in addition, make a separate provision for the determination by test of the strength of those special forms of construction to which the formula and rational theory do not apply. This course has recently been followed in the most up-to-date building codes, in order not to discourage or prohibit methods which aim at superior fire resistance, lightness, and other economies.

There is room for great improvement in the matter of test loading of floors. In the past this has not been done in a scientific manner, and the varying and conflicting results of many of the tests is largely the result of improper or so-called "fake" loading. This is a subject

Mr. Himmelwright.

which in itself can well constitute a separate paper, and is so important that the writer trusts that some one who is well-qualified will give attention to it in the near future.

Another great stumbling block in cinder concrete construction is in the definition of what constitutes a good quality of cinders. There is widespread ignorance in regard to this material, the popular idea being that it is coal ashes from ordinary stoves and furnaces, which contain from 50 to 75% of soluble sulphates and silicates in the form of white powder and comparatively soft whitish lumps.

Those who have this idea of cinders sometimes specify that they shall be screened, discarding all fine material, hoping in this way to eliminate the fine white ash, and, by retaining only the coarser portion, they expect to obtain suitable material. Ordinary coal ashes, if treated in this way, will still contain a large proportion of the soluble sulphates in coarse lumps.

Cinders with any considerable quantity of soluble sulphates are entirely unsuited for concrete aggregates, and should be prohibited. A good quality is obtained from large steam boiler plants in which the cinders are cooled by spraying. They contain practically no soluble sulphates or silicates, and from 95 to 98% of the fine material is grit fully equal to sand of good quality for the purpose of making concrete. When a building law requires screening, it can readily be understood that excellent material (the fine grit) is thus prohibited and wasted, which involves useless expense and a large loss in economy of construction. Locomotive cinders—on account of the coating of soot—and cinders from gas plants, are also unsuited for concrete. The extremely coarse clinker from bituminous coal is objectionable, as is, in fact, any coarse material.

To get uniform and satisfactory results, all cinders should be passed through rollers or crushers which will reduce them to a size that will pass a ¾-in. square-mesh screen. If sand is added to the fine material, so as to make a mixture in the porportion of 1 part of high-grade Portland cement to 2 parts of fine material and sand, and 5 parts of crushed cinder aggregate, a most excellent fire-resisting concrete will result.

A good definition for a suitable quality of cinders in a building code is the following:

"Cinders, where referred to in this code, shall be construed to mean the residue of coal consumed in large steam boiler plants, free from soluble sulphates and silicates, and in which the fine material is composed wholly of grit. (Note:—Ashes or cinders from ordinary coal stoves, ranges, hot-air furnaces, small steam boilers, or locomotive or gas-plant cinders, shall in no case be used for aggregates for cinder concrete.)"

An imaginary difficulty with cinders is the large quantity of unburned coal they are supposed to contain. Some years ago, in the

writer's experience, work on one of the largest buildings in New York City was suddenly stopped by the architect. His inspector happened to be in the basement one day and saw a considerable quantity of black particles in the cinder. Cinders of the same quality had been used on the entire job, which was then half completed. The foreman in charge of the fire-proofing endeavored to satisfy the inspector by explaining that not all the black particles were unburned coal, but the inspector insisted that the work be stopped forthwith, and the architect so ordered. The inspector then selected a quart of the black particles from the cinder pile, took them to his own chemist, and had an analysis made. The result was that only 7% of the particles selected were found actually to be coal, and 93% consisted of stone, slate, and other impurities resembling coal. Although there appeared to be as much as 10% of unburned coal in the cinder supply, this analysis proved that there was in reality less than 1 per cent. Mr. Himmelwright.

The foregoing are a few special features and conditions which the writer has noted in his experience in connection with cinder concrete fire-proofing. He has not attempted to go into the matter thoroughly, or in any detail, as he has not the time or opportunity to do so; but attention is called to these features of the problem in order to indicate that it is larger and more complex than is realized by the average person, especially by those whose experience is limited to a few tests made with the ordinary forms of reinforcement, and who consider only the question of strength.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

REINFORCED CONCRETE DOCKS: FOREIGN AND AMERICAN STRUCTURES. FAILURES, COSTS, AND GENERAL CONSIDERATIONS.

Discussion.*

BY MESSRS. J. J. H. MUIRHEAD, W. J. BARNEY, EUGENE W. STERN, R. D. COOMBS, JOEL J. PEMOFF, WILLIAM GOLDSMITH, DEWITT C. WEBB, JOSHUA F. RAMSBOTHAM, AND CHANDLER DAVIS.

Mr. Muirhead.

J. J. H. MUIRHEAD, M. AM. SOC. C. E.—In regard to concrete dock construction, the speaker always looks on Para as one of the examples of what not to do. While there, he calculated that, approximately, £5 000 000, sterling, had been spent for the accommodation of five ships. Of course, that calculation is not altogether fair, yet it is not unfair, because it illustrates a system of finance radically different from that which is customary in the United States. In fact, it is a system that would not be tolerated in American undertakings. It is true that comparatively little more money was required to complete the work, which now accommodates a large number of ships, nevertheless, the initial outlay was enormous, and quite unwarranted by the results.

The speaker regrets that as a Society we spend too much time in the discussion of details and do not study the general schemes as we ought. He knows of no justification for the construction of such expensive port works at Para, beyond the fact that the concessioners and contractors made a profit. True, the civil engineers made something, also, but not by any means enough to compensate for some forty lives lost by yellow fever. Quite a brisk shipping business has

*This discussion (of the paper by Harrison S. Taft, Esq., published in April, 1914, *Proceedings*, and presented at the meeting of May 20th, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Muirhead.

been done in materials for the improvement of the City of Belem de Para itself, but that is temporary.

The only trade that Para has, or is ever likely to have, is rubber. Are not our friends, the mechanical engineers, doing all they can to devise substitutes for rubber? It is being planted in many countries. The conditions under which it is obtained in Para and the neighboring States are so bad that it is a very precarious industry. The fluctuations in price are great, taxation is unreasonable, and "ladrones" are only too common.

The chief work at Para consisted in a bulkhead wall, built on the "slice block" principle, extending along one bank of the River Amazon, in front of the city, which provided 35 ft. of water alongside the wall. The speaker cannot see that this system was at all suitable for the conditions to be met on the Amazon. The glaring defect was the absence of stone with which to make concrete. Cement was imported from England and sand of excellent quality was obtained a day's journey down the river. The blocks were made of cement and sand only.

At the same time, clay suitable for brick-making was being dredged immediately in front of the wall and disposed of at sea or in the deep parts of the Amazon quite a distance away. From experience gained by the speaker in Kingston, Jamaica, and from the opinions of men who worked there when that city was being rebuilt after the earthquake, much the finest concrete-making material one can have is broken brick. On one occasion, the speaker had to remove some broken-brick concrete, and although it had set only a comparatively short time, the difficulty of removal has given him a very great respect for concrete of this class. He has never heard of making brick and deliberately breaking it up when almost new as a substitute for gravel or broken stone. Under given conditions, the experiment should have been made. The design contemplated 30-ton blocks. Had they been made in the proportion of 1 part cement, 2 parts sand, and 4 parts broken brick, a great saving would have been effected over 1 part cement to 2 or even 3 parts sand.

In some places, stone for ballasting was necessary. In these cases, a very fair grade of iron ore was used. This was also a waste of good material. Again, the speaker would suggest broken brick, even when the brick has to be made and then broken by mechanical means.

Mr. Barney.

W. J. Barney, Assoc. M. Am. Soc. C. E.—This paper serves at least one purpose, in that it places data relating to dock construction before the members of the Society. The great problem in such construction is concrete *versus* timber, and Mr. Taft has gathered together original references and made suggestions as to where information thereon may be obtained. The paper represents weeks of compilation in the library and by correspondence, and involves a great deal of hard research

work. The speaker hopes that it will be given the benefit of careful discussion of the many points involved in concrete *versus* timber pier construction and a combination of concrete and timber piers. Mr. Barney.

In Portland, Ore., it was a great question whether concrete or concrete and timber combined should be adopted. The city is in a timber district, yet the necessity of avoiding fire risks seemed to compel the use of concrete, and a combination of timber below the water line with concrete above that was used in order to avoid such risk and, at the same time, to keep down the cost. To the speaker, the great question in such matters has always seemed to be the "commercial life" of the piers; that is a vital factor which is frequently ignored. In foreign ports, pier construction has had practically to be dynamited out, because its "commercial life" had passed away and new construction was necessary for larger vessels and changed conditions.

These questions should be considered and discussed more widely than they have been, particularly in connection with this paper.

EUGENE W. STERN, M. AM. SOC. C. E.—There are some general considerations in this paper which it might be well to review carefully. Mr. Stern.

It will doubtless be conceded that it is desirable in many cases to substitute a more durable material than wood for docks and piers, provided the cost is not prohibitive, and its permanency in sea water can be assured.

Mr. Taft has gone to a great deal of trouble to gather information and present it in concise form, but he treats rather indifferently the fact that in the United States there have been some serious and disastrous experiences with concrete structures in sea water. He cites many cases in which concrete has stood well, but does not dwell sufficiently on the failures.

Some 10 years ago, the speaker's attention was first called to the disintegration of concrete in sea water on some pier work in the lower part of the Hudson River. Since that time he has been following this subject carefully, with the result that he is convinced that there is as yet considerable uncertainty as to the action of concrete in sea water, and until that uncertainty has been removed, engineers must go slowly.

At Atlantic City quite a number of concrete structures are exposed to the action of sea water. A few years ago, the speaker investigated the condition of almost all these structures. It was just about the time when the large cylindrical concrete piles were being sunk for the Boardwalk, but the speaker has not been able since to examine these particular piles. Every structure in Atlantic City that the speaker examined, from one end to the other, which came in contact with sea water, showed more or less deterioration, and it is believed

Mr. Stern.

that any one with open mind, who went there to investigate, would be similarly convinced. The reinforced concrete structures built over the sea showed, not only the effects of frost and the action of waves, but also chemical disintegration.

There are at least three kinds of action which may cause deterioration in concrete structures exposed to sea water:

1.—The effect of the impact of the waves;
2.—The effect of frost;
3.—The effect of chemical action.

At Atlantic City, it seemed to the speaker that a great deal of disintegration was due to chemical action. In places the concrete had cracked so much that the salt water had penetrated to the reinforcement, which had rusted badly. The concrete had also swelled and cracked off in places. In one of the large piers, built a few years ago and projecting into the ocean, the piles had shells of boiler iron, 18 in. in diameter, riveted together. These had been sunk and then filled with concrete. At the time the speaker examined this pier (probably then about 10 years old) nearly every one of the cylinders had been split open by some great internal pressure, due without doubt to chemical action having taken place in the concrete, caused by sea water entering through the joints of the shell, which were not caulked. Many vertical joints in the iron shells were burst open and the rivet heads sheared off. The joints had opened to such an extent that part of the concrete filling could be raked out, and was found to be almost in a powdered condition.

A series of valuable experiments is now being made by the Aberthaw Construction Company, of Boston. About 5 years ago, twenty-four square piles, about 16 by 16 in. and 16 ft. long, were prepared. These were placed in the sea at the Charlestown Navy Yard, their tops being about 18 in. out of water at high tide, and their bottoms about 4½ ft. under water at low tide, the mean tidal range being 10 ft. These piles were examined in December, 1913, after having been in place about 5 years. The published report of the Aberthaw Construction Company shows that only one of these twenty-four piles did not show disintegration of some kind. One pile was eaten through; others were eaten into 4 or 5 in.; others showed slight defects on the edges only.

The one pile which stood the test was made of German iron-ore cement of a rich wet mixture, namely, 1:1:2. Other piles made of the same mixture, but of a native cement, stood well, but showed some disintegration. Now, the question arises, what will the result be after 20, or 30, or 50 years?

These tests prove that the cement chemists and manufacturers must give the engineer a cement that will better withstand sea water.

Mr. Stern.

It is all very well to say that concrete docks should be built. The speaker believes in having permanent dock structures, if they can be built economically, and with reasonable assurance that they will last, but there must be this assurance before such construction is undertaken on an extensive scale.

There is no doubt that something better than wood is often very necessary. On the Pacific Coast, the speaker has seen large piles which have been completely cut through by marine borers in a few months.

Engineers are very anxious to get something better than wood for this purpose, and if German cement makers can produce a cement which, at the end of 5 years, shows no disintegration in sea water, those of America should be able to do as well.

The author brings up the question as to the effects of frost on masonry structures in the Great Lakes. The speaker has observed that in the lock at Sault Ste. Marie, on the Canadian side, the walls built of limestone show, at the water line, disintegration due to frost. The stone seems to be rather porous, and in some places the cavities are several inches in depth. There is no doubt that, wherever concrete is porous, frost action will be more or less harmful, so that it is necessary to get a dense mixture for concrete exposed to frost action, whether in fresh or sea water.

Mr. Coombs.

R. D. Coombs, M. Am. Soc. C. E.—If the speaker remembers the various reports of the Masonry Committee of the American Railway Engineering Association, the gist of all of them has been that, for waterproofing, or preventing decomposition in salt water, the main thing is to make a very dense concrete, and that is practically the summation of all other reports.

Mr. Pemoff.

Joel J. Pemoff, M. Am. Soc. C. E.—The Dock Department of New York City has been building sea walls of concrete blocks set in place under water for the the last 40 years. The cement used in these blocks is such as is usually specified for first-class work. The Department has never met with failure, or even deterioration, in any portion of this work, so far as could be ascertained by submarine examinations made by divers. Only in a very few places can disintegration be noticed, and those places are between high and low water.

The great success of the Dock Department with its submarine work is due to the mixture used, 1:2:5; to the dense surface produced on the blocks; to the fact that Portland cement of the very best quality is always specified and obtained for this work; and probably also to the condition of the waters in this harbor, which carry a great deal of fine matter in suspension, tending to form a slimy coating on the blocks and thereby increasing the imperviousness of the outer skin.

One of the causes of disintegration between high and low water

Mr. Pemoff. is the fact that this portion of the work is usually deposited *in situ* while the tide is low, and the early removal of the mould boards allows the sea water to reach the concrete before it is sufficiently seasoned to withstand its effects. The disintegration of exposed concrete surfaces in New York Harbor is rather the exception than the rule.

Mr. Goldsmith. WILLIAM GOLDSMITH, ASSOC. M. AM. SOC. C. E.—Reinforced concrete piles, as well as a new type of reinforced concrete bridge resting on piles, have been used in many places throughout the Philippine Islands. These piles are usually 16 by 16 in., approximately 40 ft. long, and have a 1½-in. steel pipe running through their centers so that they may be jetted into place. Pantal and Calmay Bridges, being, respectively, 300 and 600 ft. long, are on piles of this type.

There are five piles in a bent, and the bents are 20 ft. from center to center. Reinforced concrete girders rest on these piles, the bridge being designed to support a 12-ton road roller.

These bridges have been in use about 5 years, and many more have been built. They have stood the test of salt water very well, and show no deterioration due to this cause. The cement used in their manufacture is "Green Island cement," made in China, the concrete mixture being 1:2:4.

Wooden piles in the same locations have lasted only 2 or 3 months. The teredo is very active in these waters, a wooden pile bridge being hardly completed when the work of the teredo would be so evident as to make the structure dangerous. It would seem, therefore, that wooden bridges have no place in Philippine waters and that concrete is the only lasting material which can be used for such structures.

The type of bridge referred to is also particularly adapted for Philippine construction on account of its low cost in comparison with that of arch bridges of wood or even of steel, the life of which is also of short duration.

Great care is taken in the testing of Portland cement in the Philippine Islands. The "standard method for analysis of cement, proposed by the Committee on Uniformity in Analysis of Materials for the Portland Cement Industry," is used. In the field, each district engineer has sufficient apparatus to make 24-hour and 7-day tensile tests, thus giving an independent check on the cement inspection.

Mr. Webb. DEWITT C. WEBB, M. AM. SOC. C. E. (by letter).—This paper is a valuable compilation of information in regard to concrete structures in water, particularly in sea water.

Some of the author's statements in regard to the deterioration of concrete in Boston Harbor are not in accordance with the writer's observations. The author, in laying stress on the action of frost in disintegrating concrete, states: "In Boston Harbor 12° below zero is not uncommon."* An examination of the records of the Weather

**Proceedings*, Am. Soc. C. E., April, 1914, p. 1002.

Mr. Webb.

Bureau for the 41 years, from 1873 to 1913, inclusive, shows only two days during that period when the minimum temperature was 12° below zero or lower. During the same period, there were only 121 days, or an average of less than 3 per year, when the minimum temperature was zero or lower.

The impression conveyed by the author, that frost has been the principal cause of the disintegration of concrete structures in Boston Harbor, appears to coincide with the general opinion. During the past 5 years, the writer has had opportunities for careful examination of many of these structures, and has supervised repairs to several of them. The result of this experience has been the formation of a very firm opinion that although frost and wave action have had some effect, the principal destructive agent has been chemical action. If frost were the most active destructive element, the concrete behind and adjacent to the disintegrated areas would, it is thought, be sound and hard. In several instances this was found not to be the case. On the contrary, the concrete which was cut away to permit a new facing to be applied, was soft, and, so far as could be determined, this condition extended through the entire mass. Pockets and streaks of a white putty-like substance were found in the concrete removed. This material was chemically active to such an extent that it burned the hands of the workmen. Neither the appearance of this substance nor the manner in which it occurred suggested that it might be laitance, nor does its chemical composition, as given below, appear to indicate such an explanation:

	Percentage.
Lime (CaO)	31.11
Carbon dioxide (CO_2)	9.63
Silica (SiO_2)	8.87
Sulphuric anhydride (SO_3)	6.68
Magnesia (MgO)	5.35
Iron and alumina oxides	4.38
Insoluble residue	5.86
Combined water	12.05
Moisture	13.66
Salt and undetermined	2.41
	100.00

The cement used originally in this work was a well-known brand, and the records of the chemical analyses show the following average results:

	Percentage.
SiO_2	22.50
$(Al_2Fe_2)O_3$	9.55
CaO	61.98
MgO	2.80
SO_3	1.33

Mr. Webb.

It appears to the writer that these statements tend to confirm the theory that the chemical action of sea water on concrete is due to the flux and reflux of the salt water in and out of the voids, gradually causing magnesia hydrate to form and abstracting the lime from the cement. It is only when concrete is porous and exposed to the unbalanced or intermittent action of sea water that trouble occurs, as it is the continuous percolation and renewal of the sea water which does the mischief. For this reason concrete below low tide is usually secure.

The remedy is not chemical, but mechanical. The sea water must be prevented from penetrating the concrete. This can best be done by the use of a dense, rich mixture, placed wet. It is desirable, when possible, to permit the concrete to harden before exposing it to sea water, but this is not absolutely essential, as can be proved by concrete structures in Boston Harbor which were not pre-moulded or built inside of coffer-dams.

The damage to the concrete sea wall, at Lynn, Mass., mentioned by the author, is believed to be due almost entirely to the pounding of the waves and wave-borne materials such as driftwood, pebbles, and larger stones from the beach. The repairs by the cement gun, when last observed, did not appear to the writer to be entirely effective. This might be expected, as the repair work was largely near low-water mark, and the rising tide would bring the repaired areas within reach of wave action shortly after the cement-gun plaster was applied.

The writer believes that concrete, properly proportioned, mixed, and placed, is an entirely suitable material for structures in sea water in any climate. It is desirable, however, to provide a thin facing of stone, hard brick, or similar material between high and low water, where it is exposed to destructive action from waves and wave-borne objects.

Mr. Ramsbotham.

JOSHUA F. RAMSBOTHAM, M. AM. SOC. C. E. (by letter).—Mr. Taft is to be congratulated on the clear and concise conclusions which he has drawn from his evidently deep study of the experiences of all nations in the use of ferro-concrete as applied to marine works.

The writer agrees with the conclusions drawn, and would like to observe that, as far as he is aware, there is no other paper or book which covers, to the same extent, the large range under review.

In regard to the use of cement under sea water: It was the writer's privilege to remove 68 404 cu. yd. of concrete, made in the earliest days of Portland cement concrete, in the Port of Liverpool, while acting as Resident Engineer on the Brunswick Dock Extension. The concrete, which was almost 40 years old, was perfect, and in no single instance was there any sign of decay or shoddy work. During that period of 40 years, the work had been under sea water, the walls, etc., in the first instance having been built in the dry.

Mr. Ramsbotham.

It is the writer's firm conviction that in building graving docks, walls, etc., it is unwise to place freshly mixed concrete in water, for the reasons given by Mr. Taft.

It is doubtful whether true reasoning has been observed as regards the Cattle Wharf at Liverpool, the deck being a considerable height above the water, and the writer cannot help thinking that "bloom" on the steel may have been the cause necessitating repairs. The author has not mentioned this important factor in the problem, but it is an absolute necessity that all bloom, dirt, or rust, should be removed before concrete is placed in the forms; if a skin of bloom is on the steel, the cement does not reach the metal, and trouble may be expected in the future.

The writer does not agree with the four conclusions drawn by an English engineer, as ferro-concrete work is certainly not indestructible, either from fire or shock, and, further, it is by no means easy to repair, in fact one can hardly conceive a more difficult job than the repair of a partly destroyed ferro-concrete structure; it would resolve itself into points, wedges, and hack-saws, and under water it would surely be most difficult.

Ferro-concrete has its proper sphere of usefulness as applied to marine works, but, at the same time, and surely to a large extent, the question is resolved by prime cost and permanency. At Liverpool, ferro-concrete was approached by Mr. Anthony G. Lyster, then Engineer-in-Chief to the Mersey Docks and Harbour Board, with care and caution, and all the work was done in such a manner that it was under review, and under no extreme circumstances could it interfere with the traffic of the Port. The policy was to make M. Hennebique not only responsible for the design, but also solely responsible for carrying out the work in a suitable manner. At the same time, Mr. Lyster had his own independent staff, who supervised and checked everything.

The writer maintains that the design cannot be separated from the execution, and that a dual control results in extravagance and inefficiency, possibly accompanied by disaster.

Mr. Davis.

CHANDLER DAVIS, M. AM. SOC. C. E. (by letter).—This paper, covering, as it does, the most important structures of the world, is most interesting and valuable, and deserves the careful study of engineers who are interested in this subject.

The most vulnerable part of maritime structures is that which lies below high water, as the materials are exposed to the action of water, which, as a rule, is not over clean. Most harbors are near or in large cities which generally empty their sewers into the rivers or bays on which they are located, and thus docks and other structures are exposed to the action of, not only sewage, but also of refuse discharged by factories, chemical works, and similar plants. These

Mr. Davis.

local conditions must be taken into consideration in drawing the specifications under which the materials are furnished and inspected.

The laboratory testing of the materials is as important as the field inspection, and should not be neglected. It is not sufficient to see that the plans are properly carried out, but every effort should be made to see that the supplies conform to carefully drawn specifications. These should read so as to cover every test to insure the use of only first-class materials, suitable for the work in view, and acceptable to the engineer. The contractor should be obliged to have sufficient material on hand to permit of a thorough test and inspection before it is used in the work. This applies especially to cement, and none should be permitted to be used under the 24-hour test. In fact, if it is possible, the cement should be held 28 days, or even longer, in order to determine its increase in strength over the 7-day test. This is important if the concrete is to be used in water, and especially if an impervious wall is required, such as would be the case in the construction of a dry dock.

Many specifications state the component parts of which the materials should be made. This, in certain instances, can be done, but, on the whole, it is safer to limit the quantities of those ingredients which, necessarily, must be a part of the finished substance, but are to an extent injurious, and leave the rest to the manufacturer. By using only well-known and thoroughly tested brands, in which the injurious components have been reduced to a practical minimum, the engineer obtains the quality and durability for which he is looking. The fact that known and tried supplies are being furnished does not relieve the engineer, however, of his duty as an inspector, and he must still insist on clean, pure materials, free from all foreign matter and substances which are likely to injure the material and impair its strength and durability, and that they should be free from adulterants, which, perhaps are harmless in themselves, but have no special value.

The engineer should insist on the use of the best and only first-class materials, and should see that all analyses and tests are carefully made by competent assistants, reserving for himself alone the right to accept materials, which, although they do not quite conform to the specifications, may, in his opinion, be satisfactory.

Reinforced concrete has been used extensively throughout the world, and with great success. There have been failures, but the general results have been good and satisfactory.

The use of concrete and reinforced concrete in dock work is increasing annually. It has been applied to quay walls, storage and cold storage warehouses, piers, and piles. Great care, however, must be used in making, manipulating, and placing the concrete, for, if used in salt water, it must be made impervious; this also applies to concrete placed in fresh water. In order to obtain impervious concrete,

Mr. Davis.

the percentage of mortar in the mixture should be larger than that of the voids in the stone, and the quantity of cement in the mortar should never be less than one-half of the quantity of sand. If this is done, the mortar will fill all the voids in the stone and properly cover it with mortar, the concrete will then set properly, the mass will be thoroughly cemented together, and the structure will be impervious to water. In certain instances the face of the work may be protected by a layer of richer concrete. Assuming a quay wall to be built of 1:2:5 concrete, the proportions in the outer 18 to 24 in. which is exposed to the action of the water, would be 1:2:3. This richer concrete will resist the flow of water through it, and the weight of the whole wall will carry the superimposed loads and resist the pressure due to the filling behind it. The engineers of the Liverpool docks have used concrete in salt water for more than 40 years, and their experience has been that it will resist the action of salt water if properly made and deposited, *en masse, in situ.*

The Dock Department of the City of New York has also been using concrete in the sometimes salt, sometimes brackish, but always dirty, waters of the North and East Rivers for more than 40 years. An examination of the sea wall shows no deterioration, the concrete being as firm and solid as the day the blocks were set. This wall, however, was built of blocks manufactured on dry land, and not placed in the work until they had hardened sufficiently to be handled with safety. Each block weighs about 75 tons. As the concrete is protected, from a level 2 ft. below mean low water up, with a granite veneering, there is no way of determining how the material would have worn if it had been subjected to contact with the ice.

Pier No. 1 (New) North River, which was built about 40 years ago, rests on concrete piers and arches; only the outer faces are protected by granite. The arches under the dock, however, are badly pitted and scarred at about low water; this concrete was laid *en masse, in situ.*

In the early Seventies this Department had little success in depositing concrete under water directly in the work, and this method was soon abandoned; then the old scheme was taken up, of building the blocks on dry land and setting them in the work with a derrick.

A very interesting and instructive example of the failure of a concrete graving dock occurred in Aberdeen, Scotland. The dock was opened in 1885 and immediately showed signs of leaks, which gradually grew to be so bad that, in 1887, a thorough examination of the structure was made. Mr. Philip J. Messent, who was called in as consulting engineer, took samples from various parts of the dock, and in his report states that the deterioration existed chiefly in those sections where the proportions of sand to cement exceeded the ratio of two to one. In some places the mortar was a mixture of more than 1 part of cement to 3 parts of sand. Mr. Messent also found that

Mr. Davis.

the mortar plastered on the surface of the concrete, which was mixed in the proportions of 1 part of cement to 1½ parts of sand, had hardened thoroughly, and was in very good condition, as was also the concrete mixed 1 part cement, 2 parts sand, and 4 parts broken stone. The failure of this dock was due undoubtedly to the laxity of the inspectors on the work, who permitted the use of a mixture which, although composed of cement, sand, and broken stone, could not be called concrete. As the concrete was not impervious, the salt water penetrated it quite freely, and changed the composition of the cement, which resulted in failure. Samples were cut out of the concrete and sent to Professor Brazier, of Aberdeen University, to be analyzed. It was found that the deterioration was due to the chemical action of the salt water on the cement. Professor Brazier says:

"The analyses of the series of decomposed cement show a remarkable difference to the original cement, inasmuch as that in all these samples there is found a large quantity of magnesia, and a large proportion of the lime in the form of carbonate. I believe this alteration is brought about entirely by the action of sea-water upon the cement. There is no other source for either the magnesia or the carbonic acid."*

Every engineer should direct his energy toward obtaining an impervious concrete, especially in the case of graving docks; and, as it is possible to make concrete water-proof, and such concrete has proven to be the more lasting, the extra time devoted to obtaining this end is well spent.

The dry dock built by Luigi Luiggi, M. Am. Soc. C. E., for the Argentine Government, at the Naval Station at Bahia Blanca, was put in commission in 1902. This structure is perfectly tight, and has not shown any signs of deterioration or leakage.

The greatest care, however, was taken in making and placing the concrete in this work. Each delivery of cement was thoroughly tested before it was used. The proportions laid down by the specifications were strictly adhered to, and the joints between the various layers of concrete were carefully manipulated at the beginning of each day's work, so as to avoid all chances of leakage at these points.

In order to insure a good concrete, the proportions having been determined, the cement, sand, and broken stone must be carefully gauged and thoroughly mixed, so that each particle of stone will be surrounded by a coating of mortar. The mixing is best done by a machine, if large quantities of concrete are to be laid. There are many kinds of such machine on the market. All have their good points, and the engineer should decide for himself which mixer is best adapted to his particular work.

* The results of the investigations will be found in full in *Minutes of Proceedings*, Inst. C. E., Vol. CVII.

Mr. Davis.

The consistency of the concrete, again, is a matter of opinion and judgment, some engineers prefer it very liquid, others require it to be dense. In the latter case it is essential to tamp the concrete thoroughly after it has been laid in place, and the layers should not be more than 6 in. thick. In the former, the concrete will take care of itself, and the tamping is not so important. In either case, whether wet or dry concrete is used, great care must be taken to make a strong and tight joint between old and new work. To do this, the surface of the old concrete should be roughened by picking, and thoroughly cleaned and moistened; a layer of rich mortar, from 2 to 3 in. thick, should then be placed on the clean surface and the new concrete should be thoroughly tamped into the fresh mortar bed. In this manner, a good junction between the old and new work will be obtained, which will not cause trouble.

It is frequently necessary to lay concrete in cold weather. Although it is not advisable to do this, it may at times be necessary to push work to completion in spite of the low temperature. In order to prevent the concrete from freezing, some precaution must be taken, either by maintaining fires in stoves or by raising the temperature with steam coils, according to the location and magnitude of the work. On the other hand, it is just as important to protect the concrete from the direct rays of the sun, and prevent the water in the mixture from being evaporated during very hot weather, or the concrete will not set properly, will not gain its full strength, and the surface will be likely to crumble. Frequent watering of the surface of the concrete with a spraying nozzle, and covering the surface with moist sand, saw-dust, or canvas tarpaulins, will prevent the water from being evaporated, and the concrete will set properly.

Frozen concrete will in time thaw out and eventually set. The following may be of interest, as it shows what may happen to frozen concrete; although it is not intended to indicate by this experience that concrete should be allowed to freeze, even when being built in as large masses as the blocks mentioned. It was found necessary to move some concrete blocks, which were about 10 ft. 6 in. by 6 ft. 8 in. by 8 ft. and had been built in freezing weather. According to custom, the work of concreting was stopped as soon as the temperature in the moulds fell to 36° Fahr. The blocks had been completed and allowed to stand for 6 or 8 days, when it was decided to shift them to make room for more work. Chains were rove through the chain holes, and, as the attempt was made to lift the blocks, the chains cut through the concrete. It was found that small crystals of ice had formed in the concrete, and that the process of setting and hardening had stopped. The remaining blocks were left undisturbed until the following spring, when they were handled and set in the sea wall without further trouble. These blocks behaved well and showed

Mr. Davis.

no sign of having deteriorated, although built at the same time as the two which broke in handling during the cold spell. This experience does not indicate that concreting should be carried on during cold weather without some precaution being taken to prevent freezing, but that, if concrete, in large masses, once frozen, is left undisturbed, it eventually may thaw out and perhaps set properly. No samples were taken to test for hardness or porosity; in this case, weight was the main requirement.

It is impossible to expect good and permanent results if poor materials are used in concrete, even if laid with the greatest care, as was the case in the following illustration: A reservoir, part of a private water supply, was discovered to be leaking; in fact, it failed suddenly, and would not hold water. The conditions revealed by an examination made it all the more surprising that the structure was ever water-tight. It was built partly on rock and partly on a very hard clay. Its floor consisted of about 5 in. of concrete made with sand, gravel, and first-class American Portland cement. The sand and gravel contained a very large percentage of clay, loam, and foreign matter, nearly 50% of their ingredients being injurious to the concrete. The old floor was easily removed, being readily picked up; in fact, the clay under it was considerably harder than the concrete; its appearance at first glance was good, it was apparently smooth and hard; on a closer examination, however, a large number of soft spots were located, and the entire surface was found to be pitted.

The sand used was reported to have come from a sand bank which furnished the materials to be used in the repair work. This can readily be believed, as the sand and gravel, after being screened and washed, yielded about ¼ cu. yd. to the load of 1¼ cu. yd., and in one case 1 cu. yd. of sand shrank to about ⅛ cu. yd. after being screened and washed.

It is the use of such materials that condemns concrete, and probably is the cause of most of the failures which are reported from time to time. Absolutely clean materials should be insisted on, and none other permitted to enter into the mixture placed in the work; in no other way can satisfactory results be obtained.

If it is intended to use reinforced concrete, great care must be taken that the plans are properly carried out. It is essential to place the reinforcement just as the design shows it. Numerous failures can be attributed to placing the steel in the forms without any attempt to make the reinforcement conform to the drawings. To do this means care on the part of the inspector, and no concrete should be permitted to be placed in the moulds until the steel skeleton has been carefully examined, accepted as placed, and passed on by the inspector. This is essential, especially when one considers the carelessness of carpenters, who make no attempt to remove from the forms pieces of wood, no matter how large. These, being enclosed

in the concrete, naturally weaken the structure. It may or may not fall, but, usually, it will develop weak points. Mr. Davis.

In the concrete of a building which collapsed several years ago, were found, not only pieces of wood, but a large assortment of foreign matter, such as a pair of overalls which evidently had been placed in the form for safety, was forgotten, and eventually became part of the structure. It is such accidents, all due to carelessness, that have prevented a more rapid development of ferro-concrete construction in the United States.

Constant vigilance is necessary to insure good work and to obtain as nearly perfect results as possible. The entire work must be based on carefully drawn plans and specifications, and it is essential that they be followed faithfully.

THE POSSIBILITIES IN BRIDGE CONSTRUCTION BY THE USE OF HIGH-ALLOY STEELS.

Discussion.*

BY MESSRS. E. L. CORTHELL, W. H. WARREN, DAVID A. MOLITOR, SIR BRADFORD LESLIE, JOHN C. FERGUSSON, AND V. E. DE B. DE BROË.

E. L. CORTHELL, M. AM. SOC. C. E. (by letter).—There is no doubt that the spans of bridges are increasing in length and that there are many locations where the kinds of steel described and treated in this paper would be used to bridge over wide expanses of water not now possible, if they could be manufactured at a reasonable price. Mr. Corthell.

All engineers who are contemplating such structures will take great interest in the author's suggestions. It is to be hoped that the funds necessary for the suggested series of experiments may be found. The results would be of use, not only in the United States, but elsewhere, such as, for instance, in the proposed cantilever bridge over Sidney Harbor, Australia, the main span of which is to be 1 600 ft. long and 94 ft. wide between centers of posts, for four railway tracks, main roadway, motor roadway, and footway. Mr. Bradfield, the engineer, is soon to be in America, and this paper will interest him.

The extra price of 2 cents per lb. asked by manufacturers for the proposed high-alloy steel would restrict its use, but if it was called for by engineers, in sufficient quantities to warrant its general manufacture, no doubt the price would be cut in two, as the author indicates.

The author's remarks on page 680† about live loads are quite important. He states that:

"The live-load stresses on the main truss members will never be quite as great as they are computed, because, first, the trains on the two tracks never advance together so as to produce maximum web

* Continued from May, 1914, *Proceedings*.

† *Proceedings*, Am. Soc. C. E., for March, 1914.

Mr. Corthell.

stresses; second, such trains are not likely ever to cover entirely the bridge or any individual part of it, except, perhaps, the central span; and, third, it is improbable that any load of cars, unless they be ore or coal cars, will ever be uniformly full and loaded to the assumed limit."

All of which is true and might well be taken into account in the actual design of long-span railroad bridges.

It is customary at present to allow for a train load of 5 000 lb. per lin. ft. (from 3 000 to 3 500 lb. per lin. ft., 20 years ago). Not many cars weigh (loaded) 5 000 lb. per lin. ft., and these are not often loaded to their full capacity. A car having a capacity of 100 000 lb. will weigh about 50 000 lb., and is 40 ft. long. This brings the load to 3 750 lb. per lin. ft., which is not much more than that allowed 20 years ago. Are designing engineers expecting still larger cars than at present? It would seem almost impossible to increase the loads per linear foot to more than those which now obtain.

Certainly safety should be the desideratum, but if the dead load of a bridge can be decreased materially by using judgment in the application of live loads in designing, a great deal of money would be saved, so much, in fact, that cases might arise where the difference in cost would make practicable a project which otherwise might be impracticable.

This, and substituting for carbon steel a steel of a "high, cheap alloy, suitable in every particular for bridges", which, the author says, "is now before metallurgists and the builders of large metallic structures," may reduce weights and consequent costs to such an extent as to be of immense advantage in the projects of railway bridges of long spans.

The author is right in his statement that "the onus is on the Engineering Profession to see that the necessary experiments are arranged for." It is to be hoped that the paper will receive the discussion that its importance and character deserve.

Mr. Warren.

W. H. WARREN, M. AM. SOC. C. E. (by letter).—This paper is of unusual interest to the writer, as it is proposed to build a cantilever bridge over Sydney Harbor of 1 600 ft. span. In giving evidence before the Public Works Committee of New South Wales, in May, 1912, he strongly advocated the use of nickel steel in the cantilevers and suspended girders, with carbon steel in the floor-beams and stringers, and also in the systems of bracing. He also directed attention to Mr. Waddell's paper* on "Nickel Steel for Bridges," as supporting his own argument that considerable economy would result in the use of nickel steel on account of its higher elastic limit, and the fact that it can be worked under all the necessary manipulations in the shop in

* *Transactions*, Am. Soc. C. E., Vol. LXIII, p. 101.

a satisfactory manner, and also that its other physical properties are at least as good as carbon structural steel. Mr. Warren.

If an alloy steel could be produced having an elastic limit of 70 000 lb. per sq. in., with its other necessary qualities suitable for bridge work, at a moderate cost, a great advance would at once become possible in the art of the bridge builder, so far as the design of long spans is concerned. The paper shows that such a material may be reasonably anticipated in the future, provided sufficient inducements are given to the metallurgist and the steel manufacturer, and the greater economy that would result in the use of steel having a still higher elastic limit is clearly indicated in the diagrams which have been worked out in such a painstaking and elaborate manner. The paper is most opportune, and it suggests and indicates the probable method of procedure in a line of research which, it is hoped, the metallurgist will seriously consider. The writer is of the opinion that members of the Engineering Profession all over the world owe a debt to Mr. Waddell for the notable papers which he has contributed on the design of bridges.

DAVID A. MOLITOR, M. AM. SOC. C. E. (by letter).—This most interesting paper represents many years of labor and experience, and, as a contribution to engineering knowledge, should be accepted with due appreciation and regard. Mr. Molitor.

The author's conclusions relative to the advantages to be derived from the use of "high-alloy" steels in bridges, both in point of economy and greater span lengths attainable, are true beyond question, and, as pointed out in the paper, the problem of finding a suitable cheap alloy steel is now before the metallurgists and the builders of large metallic bridges.

It might be said that this problem has always been before the manufacturers, and possibly also the metallurgists, at least since the construction of the Eads Bridge at St. Louis; but, what has been accomplished, and who is most interested in progress along these lines?

Aside from a few innovations, chiefly with the aid of alloys such as nickel, aluminum, chromium and manganese, to raise the elastic limit and ultimate strength, and titanium as a purifying agent, little has been accomplished to improve the quality of steel for bridge and structural uses since the introduction of the open-hearth process. However, the two great defects in all manufactured steel are segregation and piping, for which no remedy is known to mill operators except the costly and wasteful method of discarding from 15 to 40% of the ingot, and, further, scrapping all material showing defects in the finished product. If these defects were readily discernible, this method might insure good results, but at high cost.

Both segregation and piping are local defects; the former is always hidden in the finished material, and the latter is usually invisible except

Mr. Molitor.

when it appears as a noticeable surface defect. Hence, it follows that no specifications can be written so as to insure a high-grade homogeneous material, in spite of the most painstaking mill inspection.

Engineers prescribe both the chemical purity and physical requirements for bridge and structural steel, and require that a test shall be made from a specimen taken from each ingot, and on the results of these tests the metal is either accepted or rejected, reserving the right to reject such of the accepted material as may develop defects in course of manufacture. The presumption is that all material not rejected in the mill or at the shops is uniformly good and up to the specifications.

However, nothing could be more erroneous, and, even if every single piece of rolled material were tested in like manner, this could not be accepted as absolute proof of quality. For there might be a hidden flaw or pipe, or spot of segregated metalloids, anywhere in the finished piece, which would never be revealed by any test, but might ultimately come to light through failure.

A careful perusal of the Report of the Committee on Rails, of the American Railway Engineering and Maintenance of Way Association,* will convince the most skeptical of the truth of what has just been stated.

Although segregation and piping defects are likely to occur in any or all material, they are less likely to produce disastrous results in bridges than in rails, owing to the more strenuous service of the latter. It is for this reason that ingots for rail steel are cropped about 30%, on the average, and bridge steel is cropped about 20%, on the average, with a minimum of about 12 per cent.

It should be noted that Bessemer steel is less subject to piping than is open-hearth steel, and that the latter suffers less segregation than the former, owing to its lesser sulphur and phosphorus contents and lesser quantity of metalloids.

Although these conditions exist in bridge steel of the present day, their deleterious effects are largely overcome by using moderately low working stresses. It is well, however, to reflect on the conditions which would inevitably follow when the same basic material is raised to higher strength by using an alloy or higher carbon contents. Unless segregation and piping can be effectually eradicated, it would seem quite out of the question to consider high-alloy steels safe for large bridges, as defects of this class would become far more serious in slender sections with high unit stresses. In other words, a condition which might be tolerated in medium steel, might become prohibitive in the high-alloy steel.

The crucial point of this discussion rests on the willingness and on the ability of the steel manufacturer, first, to improve the quality of the present-day product by the prevention of segregation and internal

* Vol. XII, Part 2, 1911.

pipes, and second, to raise the elastic limit and ultimate strength of this homogeneous steel by the use of alloys, taking care to secure proper ductility in the high steel. Carbon might be used to a certain extent, but, in all probability, at a considerable sacrifice of ductility. Mr. Molitor.

From the manufacturer's viewpoint, however, innovations of this nature do not interest him so long as his experience is profitable and he can dispose of his entire output without difficulty. The operating department of a steel plant aims merely to produce tonnage, and the commercial department seeks to dispose of this tonnage to the best advantage.

Albert Lucius, M. Am. Soc. C. E., at the close of his discussion* says:

"The engineer must get next to the metallurgist. It is highly probable that any metallurgist who knows how to produce a better steel alloy at commercial value will succeed very promptly in getting it on the market, * * *."

This is quite an erroneous view, for it rests entirely with the operating manager of a steel plant whether or not he will interest himself in what the metallurgist has to offer, and the metallurgist, in turn, is not getting things on the market. In other words, the metallurgist, who is appealed to as the savior in this matter, is quite helpless to do anything further than possibly say he knows how the task might be accomplished.

In all the learned discussions precipitated by investigations of rail failures, the conclusions reached, by metallurgists and others possessing a wide experience in testing and inspecting steel, are that practically all the failures are due to piping and segregation. However, the only remedy proposed by our learned friends, to overcome these serious defects, is to continue cropping off the ingots until the remaining portions appear to be uniformly good and sound. These same experts when advised that the difficulty could be overcome successfully by a very simple and cheap process which would be communicated to them if they were interested, failed to go further than to acknowledge the receipt of the writer's letter of more than a year ago.

This is a fair sample of the interest manifested by those who are most in the public eye.

It may add to this discussion to enter somewhat into detail as to the phenomena of piping and segregation, as comparatively little is known with certainty, and, hitherto, all attempts to overcome these defects in steel have proved only partly successful.

Although chemical reactions of a most complex nature are known to take place between the various impurities, sulphur, phosphorus, silicon, and oxygen, with iron, manganese, and carbon, forming compounds which are known as metalloids, it is practically impossible to show the exact nature and composition of these metalloids by chemical analyses. It is also quite probable that the metalloids in the molten state are very different from those in the frozen condition. There is also a consid-

* *Proceedings*, Am. Soc. C. E., May, 1914, p. 1615.

Mr. Molitor.

erable gas formation in the interior of the molten metal, chiefly caused by the oxidation of the carbon and some of the impurities.

It is also known that the metalloids have a lower specific gravity than iron, and that their melting points are lower than that of iron, which being the case, the metalloids will cool more slowly than iron, and will naturally free themselves, to a certain extent, and on account of the difference in specific gravity will be forced laterally and upward into the lake of molten metal and continue in this action, so that the last quantity of metal that is cooled will contain a concentration of these segregated elements. The gases are similarly displaced, and, being extremely light, will hasten the collection of the metalloids into nodules which will travel upward along lines of least resistance as the metal cools in the mould. It is this effect, due to the difference in melting points, and the gravity displacement of the metalloids and gases, which gives rise to segregation and may, therefore, be classed as a physical phenomenon.

Piping is also a physical phenomenon, being caused by the shrinkage of the metal in the mould as it cools, and is the result of the following conditions: The metal is poured into the cold mould, and, as it strikes it, it chills or freezes to it at the bottom and sides, the chill being continued to the top level of the poured metal. The cooling or freezing takes place successively toward the top and center of the mould, and as the metal cools it naturally contracts and draws its supply for contraction from the molten lake in the center which sinks as the demand is made on it by the contraction of the surrounding metal, the result being the formation of the funnel-shaped cavity which frequently reaches below the center of the mould. This cavity may contain, in some instances, hanging walls or bridges, which may seal across the lower part of the pipe, resulting in a hidden or concealed pipe. This may not be detected, either in the bloom or in the finished product.

Segregation and piping are thus seen to be physical manifestations which cannot be prevented by any chemical process or treatment.

Although a chemically pure steel would necessarily be free from segregation, yet no steel, or, in fact, no metal, can be poured into an ingot mould without showing a pipe. The great necessity of freeing steel from internal pipes is thus made apparent.

The use of titanium unquestionably improves steel, and especially when added to Bessemer steel, which is high in sulphur and phosphorus, and also in gases. For this reason, Bessemer steel boils more in the mould. The addition of titanium is especially useful to quiet the metal by preventing the gas production through combinations with nitrogen and oxygen, forming light substances which rapidly rise to the surface of the ladle, purifying the steel at the expense of the titanium, very little of which remains in the steel. Hence, titanium somewhat reduces segregation, but does not affect piping.

Mr. Molitor.

More than a year ago the writer's attention was drawn to a process of casting ingots, by which the gases are all expelled, the metalloids are prevented from rising, and the steel cools gradually from the bottom upward instead of inward from the sides of the mould, thus preventing unequal contraction along different elements vertically in the mould. This is all accomplished by one operation, without loss of time in casting ingots, and at little or no expense outside of the apparatus on which the mould is placed while making the ingot casting. The process is one of forging the liquid steel by imparting vertical vibration to the mould and its contents, and is called by the inventors, Messrs. Maxwell and Lash, "The Liquid Forged Steel Process."

From the foregoing description, and the phenomena attending ingot casting, it is quite clear that segregation and piping can be completely obviated, thus making it possible to produce a perfectly uniform and homogeneous steel in which the ultimate strength and elastic limit are raised about 20% by the de-gasifying effect of the process.

The loss due to necessary discard of the ingots for bridge steel is reduced from about 20% to 3 or 4%, and, for rail steel, the reduction is from an average of 30% also to 3 or 4 per cent. This would result in an actual saving of from $1.50 to $2.00 per ton for steel production; the cost is merely an interest charge on the value of the machinery used and a small royalty on the patents, to say nothing of the far greater value of the finished product and the savings brought about by lesser rejections of the rolled steel.

That these statements are correct cannot be disputed when the tests which were made last year by the patentees are examined. Hence, the introduction of this process into the large steel mills would be somewhat of a revolution in steel manufacture as well as in the vastly improved quality of the finished product.

In the present grades of steel, defects due to segregation and internal or concealed pipes represent losses to the customer, and the visible pipe is a direct loss to the mill through discard. Hence, it is, to both customer and mill, that the introduction of this new process commends itself, and both parties should be equally interested in seeing it introduced.

However, it is more than likely that the demand for the better steel must be first created before any mill will undertake the production of such an article.

To the writer's mind, there is no question regarding the possibility of producing high-alloy steels, of the kind sought by modern bridge builders, whenever it suits the convenience of the mill manager to disabuse his mind of several preconceived views and to express his willingness "to be shown". The writer also ventures to add that aluminum, possibly with nickel, will offer the most desirable combination with steel, owing to the great ductility it imparts.

Returning to questions of design, it should be observed that our

Mr. Molitor.

present methods would suffer numerous modifications when dealing with high-alloy steels, even in small bridges, as our knowledge of secondary and impact stresses would require. Deflections due to moving loads would be increased owing to the higher unit stresses used and the practically constant extensibility of all grades of steel. Secondary stresses might not suffer much increase on this account, because the connections between slender high-steel members would be less rigid, though impact stresses might be increased because the ratio of live load to dead load would be increased along with the greater flexibility of the structure.

As discussions of this kind are sometimes fruitful in bringing about advancements in engineering science, the writer expresses his high appreciation of the author's efforts in the direction of progress, and closes with the optimistic feeling that some substantial gain in the art and science of bridge building may soon come as a reward, provided the steel makers will do their part.

Sir B. Leslie.

SIR BRADFORD LESLIE (by letter).—In India the river beds are generally alluvial for an unknown depth, and piers of bridges having to be sunk to a great depth are very costly, consequently, it is economical to use spans of considerable length, but the writer is not aware of any cases in which exceedingly long spans are likely to be required. Nevertheless, the paper is of the greatest interest to bridge engineers.

The author has fully established the necessity for experimental investigation of the problem of discovering a high-alloy steel which can be subjected to heating and working at temperatures attainable in the ordinary operations of bridge construction, without impairing its strength, and which can be placed on the market at a price moderately exceeding that of the ordinary carbon steel of commerce. Such a metal would greatly reduce the weight and cost of girder bridges of moderate spans. The percentage of nickel required is so small that it seems probable the ores will be discovered in sufficient abundance, and, if so, the demand for the material must soon result in the practical realization of the author's far-sighted ideas on bridge construction.

The writer belongs to the iron age, which is ancient history, but can well remember the relief afforded to bridge designers by the increase of 50% in the elastic limit when carbon steel superseded iron as the material for bridges, and he hopes he may live to see the further improvement that will result from the general use of high-alloy steel for that purpose.

Although the writer feels that he is not qualified to offer useful criticism of the investigations described in the paper, he desires to state that his experience ranks him among the unbelievers in the dangers of so-called "impact". If that bugbear can be dismissed, it will effect great economy in girder construction. He is equally skeptical as to the supposed injurious effects of alternating stresses which do not exceed the elastic limit.

Sir B. Leslie.

A train does not drop on to a bridge, it rolls on and off; at whatever speed it may be traveling, the pressure is applied and relieved gradually—a mass falling by gravity moves but slowly when it begins to fall—any blow there may be is due to the action of the springs. Velocity in its application does not affect the stresses distributed over a given area of material by any load. At 60 miles an hour the axle of a vehicle may be subjected to alternating stresses at the rate of 10 per sec. but not to "impact"; properly lubricated, the axle keeps cool. The worst "impact" that axles get is at worn rail joints which strike a blow felt through springs and cushions, and is the principal cause of axle failure. "Impact" is locally and not otherwise destructive. If a bar of iron, such as a 6-ft. length of rail, be suspended by one end and constantly struck four or five blows per sec. by a hammer, heat will be evolved by the superficial destruction of the metal; such destruction will be local and cumulative; the entire bar will vibrate; but, however long continued, the vibration will not affect the properties of the metal. In a similar manner, the top of a pile is punished by hard driving and the remainder of the pile suffers no injury, though it is true, the pile receives but a few hundred blows.

If bridges suffer from "impact", it must be transmitted through the rails. Rails are worn out by attrition; excepting at worn joints, there is no "impact"; millions of loaded axles rolling over rails at high velocity do not impair the strength of the metal.

Many years ago the writer made careful experiments on scrap rails before using them for structural purposes*. The rails were of iron, of the old double-headed section formerly in use in England. Pieces were cut from both heads and tested under tensile and compressive strain, also for ultimate extension and contraction of area. In no instance was it found that the scrap metal had lost any of its original properties, under millions of tons of traffic resulting, not in "impact", but in constantly alternating stresses. "Impact", indeed, there is, at the joints, causing failure of the ends of the rails.

Prior to the last 25 years, no attention had been given to "impact", and no account had been taken of it in designing girders. The writer has never met with any authentic instance of failure on that account. On the contrary, many large bridges, both of iron and steel, are now carrying axle loads in excess of what they were originally intended to carry, without any indication of failure, except in the platform system, where increased panel loading has, in some cases, involved strengthening.

The only precaution advocated by the writer to mitigate "impact" (the effects of which in short spans are injurious to the masonry abut-

* Owing to heavy rates of freight from India to Europe, scrap material which could not be rerolled or worked up in India, in about 1878, was practically unsaleable, consequently its use for structural purposes, instead of importing new material, was very economical.

Sir B. Leslie.

ments, rather than to the girders themselves), is to build bridges up to, say, 100 ft. span to carry the ordinary track laid in good ballast. This facilitates maintenance, prevents the passage of the bridge being felt on board the train, and the shaking of the masonry abutments, and saves the necessity for allowance for supposed "impact". Such saving is discounted by the girders having to be provided with flooring, and built strong enough to carry ballast. However, there can be no comparison in the comfort of traveling over a ballasted bridge carrying the ordinary track, and running over a rattling, noisy structure in which the track is fixed directly to the girders.

The writer infers, from the paper, that it is customary to build long-span bridges for double track, presumably because the increased width between the girders relieves the bending moments due to wind pressure, and improves the lateral strength of the structure generally.

If worked on a proper system, a single-line bridge will accommodate a very heavy traffic. Two trains following each other every 10 min. gives twelve trains in each direction per hour. Where intensity of traffic absolutely demands it, the expense of a double-line bridge must be met.

Instances have occurred on the 5 ft. 6-in. gauge railways in Bengal of trains being brought to a standstill and overturned by wind pressure. This indicates a side pressure approaching 40 lb. per sq. ft. over considerable areas. No such accident has hitherto occurred on a bridge in India, though it is probably what took place at the collapse of the Tay Bridge in 1869, and it is necessary, therefore, to take account of the possibility.

It is suggested that all important bridges should be equipped with a reliable anemometer interlocked with the signals, so that whenever the wind attains a velocity exceeding, say, 80 miles per hour, or 17 lb. per sq. ft., the traffic over the bridge would be stopped; considering the risk, this is only a reasonable precaution. Thus, in the case of wind pressures exceeding 17 lb. per sq. ft., the effect on the bridge would be limited to that on the structure only, below that it would be necessary to take account of the wind pressure on the train as well as on the bridge itself. Such an arrangement would enable the economy of single-line bridges to be realized wherever practicable and desirable.

Doubtless, however, all these points have received due consideration in the preparation of the paper. They are all the observations that the study of this valuable paper, considered in the light of 60 years' experience in bridge building, enables the writer to offer.

Mr. Fergusson.

JOHN C. FERGUSSON, ESQ. (by letter).—The amount of time and energy the author has devoted to his subject, and to the preparation of his valuable diagrams, showing, by comparison, the advantages of using steel of higher tensile strength in long-span bridges, shuts out all but the most friendly criticism. Yet facts are stubborn things;

we do not look at them from the same plane, so we cannot all see alike. It is this very difference of view which, in the long run, gives the real value to the exchange of ideas among civil engineers, by bringing things into true focus. Mr. Fergusson.

The use of nickel steel cannot be adopted, generally, as the best material for all classes of bridgework; its particular advantages adapt it more for use in bridges of very long span than in short ones. Its special advantages—elastic limit and tensile strength, hence lightness—over the best classes of open-hearth carbon steels, are only obtained in nickel steels of the very highest grades; and their cost would be prohibitive in ordinary structures. Carbon steels, for a tensile strength of 40 tons per sq. in., have advantages over nickel steels carrying low percentages of nickel. The open-hearth carbon steel is a more reliable product, is stronger in compression, has greater resistance to impact, its manufacture and testing are extremely simple, and the main results are constant; whereas, the testing of nickel steel during the process of manufacture is very complicated, the material is subject to great variations; and, further, the combinations of carbon, manganese, titanium, and tungsten, even in the smallest fractional percentages, produce most unlike results.

It has been found that the addition of nickel to iron causes the nickel to act as a flux on the carbon, manganese, and other minerals in combination with the iron; and the anomalous results produced vary very much more owing to slight changes in the proportion of carbon, manganese, or other metals in the chemical composition of the ingot, than in the mere change of proportion in the parts of the nickel to iron.

The idea of adopting a standard specification for nickel steel, to be used in bridgework, seems to be wrong, because the conditions required for various spans and loads are so variable. Would it not be wiser for a civil engineer to state his requirements and see that they are carried out, leaving the actual manufacture of the metal to the metallurgists and ironmasters?

To use a nickel steel of very high tensile strength, chiefly to save weight in the bridge material—unless where the conditions are imperative—would seem to be extravagant, and even unwise. There must be risk in trusting to the highest limit of tensile strength of a manufactured steel which is known to be very variable. The mere saving of weight in bridges of moderate span would hardly warrant the risk, coupled with the extra cost of material of higher grade. Standard specifications for nickel steel would be worthless unless they met the highest conditions and requirements for the longest bridges mentioned by the author. It is for bridges of this class, of exceptional length, that he hopes to find a sufficiently strong and suitable material in nickel steel.

Mr. Fergusson.

The author, in his previous paper,* states that the best percentage of nickel was found to be 3.5. The allowance of impurities in the nickel steel was put as phosphorus, 0.03%; sulphur, 0.04%; silicon, 0.04%, and manganese, 0.75 to 0.85%, which produced an elastic limit of 61 300 lb. and an ultimate strength of 99 300 lb. per sq. in. The impact was less than that of carbon steel, the relative values being 87 and 73 to 100, for low and high nickel steel.

The author also states that the nickel present in larger quantities makes the material unworkable in the shops.

If the author is still of these opinions, and if we may regard his present able paper as supplementary to his former one, the foregoing statements deserve consideration, because they do not agree with the general idea as to the chemical composition of a very high-class nickel steel that would best fill the requirements of the extraordinarily long bridges he has mentioned. The proportion of 3.5% of nickel, which he gives, appears to be too low. As he does not mention carbon in his analysis, it may be presumed that he has eliminated it; surely this is a difficult operation in commercial manufacture? This is a most important point, for, with a low percentage of nickel, the reduction of carbon below 0.20 becomes essential.

Provided the carbon is kept low, there is a constant rise in the tensile strength of nickel steel, in proportion to the increase of the nickel present, up to 12 or 15 per cent. The increase of nickel requires a decrease of carbon, together with an increase of manganese, otherwise, although the breaking load may be the same, the value of the elastic limit will fall rapidly.

The writer has pleasure in acknowledging that some of the earliest and most successful workers of nickel steel are Americans. The Bethlehem Iron and Steel Company, the Homestead Works, of Pittsburgh, and others, are well known.

There are a few points about which there appears to be considerable difficulty to agree. The author states that steel containing more than 3.5% of nickel was unworkable, yet in Sheffield they found no difficulty in working material containing nickel, 7.65%; manganese, 0.68%; and carbon, 0.17%, although it was hard.

In America there is a preference for adding nickel in iron ores, whereas in England it is preferred to add the nickel otherwise. In Sheffield it is found difficult to produce forgeable bars in the absence of manganese, and it appears to be impossible to get satisfactory results.

The writer ventures to point out two disadvantages in nickel steel for bridgework:

(*a*) The difficulty of welding, and working;

* "Nickel Steel for Bridges", *Transactions*, Am. Soc. C. E., Vol. LXIII, p. 101. Abstract in *Minutes of Proceedings*, Inst. C. E., Vol. CLXXVI, p. 345.

(*b*) The necessity of keeping the carbon extremely low—under 0.02%—whereas the fatigue resistance of steel is increased enormously by raising the percentage of carbon. Mr. Fergusson.

V. E. DE B. DE BROË, ESQ. (by letter).—The writer has read this paper with interest, and begs to offer the following remarks. Mr. de Broë.

Spans.—As compared with Indian practice, the length of the spans required in America is remarkable. The Government of India railway bridge regulation tables are worked out for spans of from 5 to 600 ft., and usually, the engineers can negotiate big sandy rivers on deep wells with girders of from 150 to 250 ft. span. The writer believes that the only railway bridge in India of greater span than 600 ft. is that over the Indus at Sukkur, which is between 700 and 800 ft. Of small spans, ranging from 10 to 100 ft., Indian railways have a great number, and additional ones are being erected daily. It is readily understood, therefore, that, with engineers in India, the use of a metal of excessively high tensile strength is not of so much consequence as it is with American engineers, faced as they are with the problem of bridging vast clefts and chasms with single openings.

Strength of Metal.—In preparing specifications, the writer works to the "British Standard Specification for Structural Steel" (revised in August, 1912), which enjoins an ultimate tensile breaking strength for ordinary girder sections of "between the limits of 28 and 33 tons per square inch." As the elastic limit is generally not less than 50% of the ultimate strength, and good firms usually work to this without extra charge, it follows that:

$$\frac{\overset{\text{Tons}}{33} \times \overset{\text{Pounds}}{2\,240}}{2} = 36\,960 \text{ lb.}$$

is the extreme elastic limit per square inch reached in practice. The author states that ordinary carbon steel is usually furnished by American manufacturers with an elastic limit of 35 000 lb., or an ultimate tensile strength of approximately 32 tons per sq. in., so that in this respect, Indian engineers are on an equal footing, and it is not until American engineers begin to mix an alloy that they get a higher elastic limit.

It is noted that the author was successful, with French manufacturers, in realizing the high standard of 45 kg. per sq. mm., equivalent to 28½ tons per sq. in., or an ultimate breaking strength of 57 tons per sq. in. Nothing of this sort has ever been heard of in Indian practice. The author also expresses himself as sanguine of reaching in America 60 000 lb. = 27 tons elastic limit, or 54 tons ultimate strength; and his researches have led him to believe that even the colossal figure of 100 000 lb. = 44 tons elastic limit, and 88 tons ultimate tensile strength, is realizable by persistent and enduring experiment until the right mixture has been obtained.

Mr. de Broë.

The writer has not had the pleasure of reading the author's former paper, "Nickel Steel for Bridges," and is not chemist or metallurgist enough to form an opinion as to what can be done in the laboratory or in small melts in the production of an alloy greatly superior in strength to carbon steel; it is obvious, however, that should an alloy ever be produced approximating in strength three times that of steel (at a commercial market value), it is not only America that will benefit, but every railway in the world will be in a position to revolutionize its bridge stress and strain calculations with a view to economizing in weight of metal.

The estimated cost of the author's proposed experiments, \$100 000 = £20 000, or even twice this sum, as suggested, is a very large one for private enterprise, but not for a Government or a group of Governments to contribute, and it is further to be noted that, should the experiments result in the success which the author anticipates, the use of the new and stronger metal could and would be extended to other forms of construction besides bridge girders. There are no millionaire philanthropists in India, and so far as that country is concerned, anything of the sort suggested would have to be done by the State.

Cost of Steel.—On page 683* it is noted that the author is handicapped with the high cost of 4 cents per lb. for steel for plate-girder spans, or £18 sterling per ton. The highest price paid in England (for export to India) during the last few years, was £13/10/0 per ton, and, even adding sea freight, it would seem that, for ironwork required reasonably near the seaboard (and not involving long railway carriage to the site of the works), London would afford a cheaper market than America.

Impact.—Impact is a subject to which the writer has devoted a great deal of study of late years, and he has come to the conclusion that it may be totally ignored, provided a working stress not exceeding 8 tons per sq. in. for steel is allowed, and a factor of safety of 4 is used.

Of course, there is much diversity of opinion on this subject in the Profession. The Government of India enjoins the use of the Pencoyd formula:

$$I = \frac{300}{L + 300} = \text{a coefficient by which the live load is to be multiplied;}$$

where L = length of loaded distance, in feet, producing maximum strain.

This gives:

In 5-ft. spans 98% of moving load,
In 600-ft. " 33% "
As against 78% } as calculated by the author's formula,
and 36% }

$$I = \frac{40\,000}{L + 500}.$$

* *Proceedings*, Am. Soc. C. E., for March, 1914.

Mr. de Broë.

The writer has recently come into possession of the Swiss Government revised regulations (issued in 1913), in which the formula for impact is:

$$2(15 - l) \text{ per cent. of the moving load,}$$

l being the span, in meters.

It is obvious from this that no impact allowance is enforced for spans of more than 50 ft., and the percentage works out: For 5-ft. spans 27% only, as against that of the Government of India, 98%, and the author's 78 per cent.

The Swiss working stress is 6.98 tons per sq. in. for steel.

The Board of Trade (England) fixes a working stress of 6½ tons for steel, which is intended to cover impact allowance. Mr. A. H. Shield, writes as follows:*

"The limiting stress of 5 tons per sq. in. for which the early bridges were designed did, in fact, provide for impact, and was fixed by the Board of Trade in 1859, some years after experiments had been made by a Royal Commission, appointed to consider the application of iron to railway structures.

"In the course of these experiments the additional strain upon bridges due to a rapidly moving load was measured by the increased deflection. A fixed permissible stress obviously failed to graduate the impact according to the span, and the allowance made in fixing 5 tons was probably insufficient for spans under 20 ft., for which at that time the use of wrought-iron was, however, uncommon. The point which it is important to bear in mind, is that the old standard admissible stresses, 5 tons for wrought-iron and 6½ tons for steel, did include an average allowance for impact, and that this should be taken into account in making a more accurate provision according to the span, or more properly, according to the shortness of the period during which the load comes upon the bridge or part of the bridge under consideration. It is only if this is neglected that the application of a graduated allowance for impact leads to a general increase in the weight of bridges.

"The sufficiency under average conditions of a factor of safety of four without further allowance for impact, is substantiated by experience in this country for 55 years; and any rules which require a greater allowance under similar conditions are indicative either of a desire to provide indirectly for the growth of the load to which structures may be subjected, or to provide a wider margin against errors of design and workmanship than has proved to be necessary under the conditions of responsibility and supervision that have obtained in the past.

"Whichever may be the motive of the authority responsible for the increased burden it is equally deserving of the attention of those interested financially in the promotion and construction of railways in our colonies and dependencies."

---

* *Railway Gazette*, June 12th, 1914.

Mr. de Broë.

The writer has not space or time to state exhaustively his reasons for recommending the total exclusion of the impact factor in bridge calculations, and perhaps the author would not thank him were he to enlarge on the subject, for a full exposition of his views would cover many sheets of paper. Briefly, however, he may say, first, that he does not think deflection tests (on which many of these formulas are based) are reliable. The following is from the Government Inspector's report on two spans of 40-ft. girders which the writer's company recently erected in Southern India:

"Two spans were tested with a B-class engine, one a dead load test and the other at 45 miles an hour. The deflection in both cases was 0.15 inch, which is very satisfactory."

This is one of the many instances.

In the second place, if a diagram is plotted, in the shape of a column (Fig. 27), and divided into three lengths represented by:

(1) A line across at, say, 8 tons (below which the girder may be loaded);

(2) A line across at 20 tons (below which is obtained an area of safety, which may be encroached on occasionally); and

(3) A line across at 32 tons (below which is represented the danger zone, never to be encroached on);

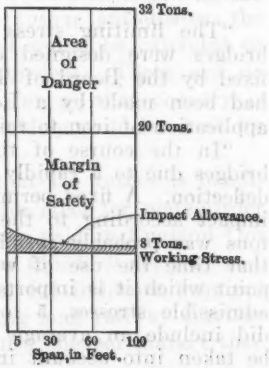

FIG. 27.

we may see how very small is the margin of risk if, above the 8-ton line, we hatch in the professional allowance for impact. We may also see how large is the margin of safety and how remote the area of danger.

In the third place, the various working stresses allowed by different authorities, and the factor of safety of four, are in themselves wholly empirical, and the writer sees no logical sequence in building, by the application of quasi-scientific formulas, on an empirical foundation. Nevertheless, he would be very interested to see the "more accurate formula" which the author has evolved from deflection experiments, mentioned on page 669,* and the data on which it is based.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

DISCUSSION ON VALUATION FOR THE PURPOSE OF RATE-MAKING.*

BY MESSRS. ALEXANDER C. HUMPHREYS, J. J. H. MUIRHEAD, CHARLES KIRBY FOX, T. KENNARD THOMSON, W. W. K. SPARROW, J. P. SNOW, E. W. JAMES, GEORGE L. DILLMAN, AND WALTER S. WHEELER.

Mr. Humphreys.

ALEXANDER C. HUMPHREYS, M. AM. SOC. C. E. (by letter).—This report is dated December 1st, 1913. The Committee reserved the right to make insertions, additions, etc. The report was presented at the Annual Meeting, January 21st, 1914, and was then referred back to the Committee for fuller consideration and to afford opportunities for further discussion.

On February 28th there was issued an "addition" to this report, written by Chairman Stearns of the Committee. In this addition the report itself is styled "The Progress Report, etc." The additional matter presented appears under the sub-heading: "Preliminary Discussion of Depreciation;" and notes attached to this statement show that it was issued in anticipation of the discussion to be had at the meeting to be held for that special purpose on March 11th, and that this addition to the report was for the purpose of "further discussing the matter [depreciation] in this report in a very elementary way." Another special meeting for discussion was held April 2d, and it is to be hoped that other meetings will be held before the report is finally presented for action.

In discussing this important report, which the writer proposes to do in some detail, he wishes at the outset to make two general statements of belief:

First, the valuation of a public utility, and particularly of a railroad, does not offer a complete solution of the rate-fixing problem.

Second, the "principles and methods for the valuation of railroad property" are the same as for the valuation of "other public utilities"

*Continued from May, 1914, *Proceedings*.

Mr. Humphreys.

only in a general way, and this report applies more particularly to public utilities other than railroads.

The writer has made an earnest and extended study of the report from the viewpoints of the engineer, the operator, the accountant, and the investigator. During all his forty odd years of experience in these four departments he has been making a particular study of "depreciation", so-called. Then, if he has failed at any point to get the meaning of the report, it has not been through lack of effort. This is in answer to the general suggestion made by Mr. Stearns at the meeting on March 11th.

The subject of the report is of vital interest to the people as a whole. If we keep in mind the fact that investors are not a class by themselves, but include presently or prospectively all those within our borders of frugal mind and intentions, we cannot escape the grave responsibility of participating in this discussion only with open minds.

Many of the reports and papers presented to professional societies fail wholly or in part to develop the truth because of lack of time and effort devoted to the discussions; let us see to it that this charge cannot rest against us in this case.

The writer finds much in the report with which he completely agrees, and much with which he can in part agree. He is sorry to say that he finds other parts with which he completely disagrees.

If the "principles and methods for valuation" as set forth in the report were adopted as a whole, the result would work grave injustice to the honest investor. The more the writer studies the report, the more he is impressed with the practical quality of certain of its parts and the excessively academic and non-practical quality of certain other of its parts. The treatment of "overhead charges" comes within the first classification, while the treatment of "depreciation" comes decidedly within the second classification.

The questions involved in the valuation of public utilities, to be solved fairly, must be solved practically. Unfortunately, these valuations appear to present many suggestions for solutions of the most academic character.

The writer will not hesitate to repeat himself; first, to meet the points as they are made in the report; and, second, to minimize the chance for misinterpretation—an ever present danger—by discussing from different viewpoints the questions as raised.

Page 6.—It is true that "during the year 1912 and since, several extended and valuable works upon this subject [valuation] have issued from the press." Mr. Robert H. Whitten's "book of nearly 800 pages" is particularly commended. The writer trusts this does not mean that all of Mr. Whitten's "clear and concise discussions" are recommended for acceptance. Some of the books referred to are more "extended"

Mr. Humphreys.

than "valuable," and particularly those written by men without actual experience.

The writer agrees that "valuation * * * must * * * be made in conformity with existing laws", but he does not agree that this necessarily means conformity with the decisions to date. In fact, this would be an impossible condition to apply, varying so radically, as do many of the important decisions. The Committee recognizes this in the statement: "the whole subject is in a developmental stage."

There is great difference of opinion as to what constitutes a "fair return". What would be a fair return in one case would not be a fair return in another. In the New York Consolidated Gas Case, the U. S. Supreme Court unanimously decided, in that particular case, because of the advantages enjoyed, or said by the Court to be enjoyed, that 6% was not confiscatory. This decision did not state that this was a fair return. This decision has been misquoted and misapplied frequently. We cannot depend safely on fair sounding words as to what constitutes a fair return.

Page 7.—Undoubtedly, the service rates should provide for an allowance for so-called "depreciation." The expenditures for renewal of plant is one of the losses of the business or costs of the service, and should be so treated. The writer does not agree, however, that in all respects "the principles are similar to those involved where one man loans money to another." The lender is not obliged to keep his money loaned to the borrower after the loan falls due. The public service corporation is obliged to keep its investment in the plant indefinitely.

The writer completely agrees with the statement that "The public may be as injuriously affected by too low as by too high rates;" but it will be difficult and perhaps impossible to so convince the public, the commissions, and the Courts, as long as engineers of standing are so wide apart as to the fundamental principles of "valuation for the purpose of rate-making." If regulation of public utilities results in the fixing of rates so low as no longer to attract new capital, the public must suffer. This is not a theory but a condition already in evidence.

Page 8.—The writer does not agree with the Committee that we should acquiesce in the action of the commissions and Courts when they announce decisions "without disclosing definitely the method by which the conclusion has been reached." Nor should we necessarily concur in the opinions of the commissions and Courts. They should be treated with due respect, but it should be borne in mind that "the whole subject is in a developmental stage," and hence the Courts yet have to be educated in the questions involved, and we cannot help in that process, as we should, unless the commissions and Courts disclose their mental processes.

Page 9.—The writer is unable to find that "deductions for depreciation" are necessarily involved in all the Court decisions. This refers

Mr. Humphreys.

to the "depreciation" which includes obsolescence, inadequacy, and physical decay, which is to be eliminated periodically by renewals of plant.

The writer agrees with the statement:

"The public should not be required to pay a return upon extravagant or injudicious expenditures; on the other hand, the rates should secure to the owner a fair return on his reasonable outlay."

However, we must not lose sight of the danger here disclosed. There will be opportunities for wide differences of opinion as to what is a "fair return" and what is a "reasonable outlay." The writer would not be surprised if there might be found, among the members of this Committee, a not inconsiderable difference of opinion on these two questions, in cases widely varying as to conditions. Consulting engineers, who, perhaps, have not had to face deficits as a consequence of their estimates, would be likely to have quite a different opinion as to "reasonable outlay" from the engineer-operator who has had to make good on his estimates.

Page 10.—Referring to the paragraph in the middle of this page, and to many other portions of the report, it is to be regretted that the Committee has not carefully and completely defined what is intended by the term "net depreciation." It will be clear what the writer means by depreciation before this discussion is completed. "Depreciation" is a term used loosely. The Committee here seems to differentiate between "depreciation" and obsolescence, though in other parts of the report it would appear that obsolescence is to be included in "depreciation" allowance. If we intend "depreciation" to cover deferred renewals, necessarily, obsolescence and inadequacy are included in addition to physical decay or exhaustion.

Page 11.—

"A valuation based upon book accounts can be kept up to date by adding to the original valuation the cost of additions and replacements made from time to time to the property, and by deducting the amounts which the corporation is permitted to earn annually to offset the net depreciation of the property."

As a mathematical proposition, this statement of the Committee would be correct provided the "net depreciation" were ascertainable by estimates made in advance; but this "depreciation" as estimated depends on many assumptions which must wait on the facts for confirmation or correction. At the best, therefore, it is only an approximation. Furthermore, the "depreciation" does not necessarily indicate any true depreciation as tested by the quantity and quality of service capable of being furnished by the plant thus depreciated. "The amounts which the corporation is permitted to earn annually to offset the net depreciation of the property" should be from the first appropriated to the renewal or replacement of plant. The corporation thus

Mr. Humphreys.

acknowledges its liability therefor, and there is no sound reason based on ethics why, pending these renewals which are necessarily of the future, the property should thus be lessened in book value in connection with rate-making. The question of rate to be charged should primarily be determined by the character of the service rendered. If the plan proposed should result in always showing a net deduction for "depreciation", as it would do in most cases, then the property might be subjected to confiscation, although in a varying amount; and if a deduction is made in cases in which the investment is thus subject to confiscation, then the amount of this deduction should be included in the original cost as an item of overhead charge. Here there would be a further difficulty, for the reason that the measure of this overhead charge, as affecting rate-making, would be a variable quantity. This variability of the amount of "net depreciation" of itself suggests the injustice of deducting therefor.

The original cost of the property should be considered in the first place as an asset. The cost of maintenance and renewal of property should be charged to a loss account. An asset account in the progress of time may be found to contain items of loss, but we need not start out to complicate unnecessarily the keeping of the accounts.

Apart from the question whether or not estimated "depreciation" should be deducted from plant valuation, the information which the Committee is looking for can be secured in better form, and in a form more available for analysis, by crediting the "depreciation" annual allowances to a renewal reserve account and later debiting to this account all the expenditures for the renewals which are contemplated in the scheme through which the "estimated depreciation" is computed. The credit balance of this account would then show the accrued "depreciation", and this would also show the avowed liability of the corporation on account of deferred renewals.

Page 12.—The writer fully agrees with the Committee that the cost-of-reproduction should not be based on a "hypothetical property of modern design, capable of producing the same results [or so claimed by the designer] as the plant to be valued."

Pages 13 and 14.—"Unused Property."—The writer agrees with the Committee that deductions should be made for surplus capacity "only in extreme cases, if at all."

As to property not actually in use at the time of valuation, it has not infrequently happened in the writer's experience that such property has been omitted improperly from the inventory; whereas, if the inventory had been made by an expert operator, it might have been evident that this portion of the plant would be required at times and perhaps for a majority of the months of the year.

Property should be abandoned in the interest of economy and good service, and every advance toward more economical and efficient man-

Mr Humphreys.

agement should be encouraged. If the profits of a company are to be limited to a low return (perhaps arbitrarily declared by some to be a "fair return") on the property actually in service at any given time, the incentive to secure the best management is weakened, if not destroyed. Under this condition, and while facing a valuation for rate-making purposes, no company could afford to abandon property in the interest of economy and good service. Any scheme of valuation that does not include property which has been abandoned in the interest of economy or good service or both, and which has not been paid for out of earnings, is defective, unfair, and against the interest of the public utilities and the public.

Page 15.—"Present or Original Conditions."—In justice, a public service corporation should be entitled to a fair and adequate return on the legitimate investment in its property. If such investment can be determined, assuming that it has been properly and intelligently made, it should not be necessary to make a valuation.

In the majority of cases it is not possible to determine the investment, and so, at present, under Court rulings, a valuation appears to be necessary. This valuation is intended to serve as a basis of rates for the future, and therefore should be made as of the present, and not on the basis of conditions of the past. In the case of the prices of copper, iron, and other materials, which fluctuate through a wide range, it is fair to assume that the future will, in this respect, as to fluctuations, be a repetition of the past, and, therefore, average prices through a term of years may fairly be used.

It is also necessary to study the events of the past to see in what condition the real estate, right of way, and other elements of the property would be, if the utility did not exist. After determining as nearly as possible the conditions that would control if the utility were not in being, an estimate should be made of the cost of reproducing the property under such conditions.

It is no more justifiable to deprive the stockholder of the unearned increment of increase in the value of his property than it is to confiscate the increase of value of neighboring property. This applies equally to real estate and to the increase in value of underground structures due to subsequent paving. The question is not what it would cost to reproduce the property under conditions varying at different times, but what it would cost to reproduce it under such conditions as would exist at the time of valuing if the property did not exist.

It may here be noted that in the recent Kings County Lighting Case, the New York Public Service Commission was over-ruled by the Court, and the cost of subsequent paving was allowed. This decision, in turn, has been reversed—another instance of disagreement among the judges on questions of principles.

Mr. Humphreys.

An estimate of cost of reproduction as a whole should not also include the additional cost of piecemeal construction. On the other hand, such cases as the New York Central Terminal serve to show that frequently it is necessary to make full percentage allowance for omissions, contingencies, and other items not represented specifically on the itemized inventory. Those who have had any considerable experience with engineers' estimates should know that bankers and business men have had too much reason for regarding these estimates with suspicion; and hence the more cautious of these guardians of the purse have been found adding considerable percentages to provide against the engineer's failure to provide adequately for the omissions and contingencies always encountered in constructions of any magnitude. Here the Profession as a whole has suffered through the lack of experience, the carelessness, or the narrowness of view of some of its members.

Page 18.—"Application of Reproduction Method of Valuation."—Though the writer disagrees with the Committee as to deduction for "depreciation" due to age, he is fully in accord with regard to inclusion of development expenses and working capital. He is also glad to note that the Committee draws attention to the fact that these and other items of construction cost are sometimes erroneously classed as intangibles.

Page 19.—"Inventory."—The Committee very properly draws attention to the fact that an inventory of an existing property does not necessarily, or even probably, give a complete schedule of the items of cost which went into the construction.

Page 20.—"Unit Prices."—In establishing the reproduction cost of a property, on first thought it would appear that, to be consistent, the unit prices prevailing at the time of valuation must invariably be used; but further thought argues for an acceptance of the view of the Committee:

"That the prices should not be fixed with reference to occasional fluctuations in the prices of labor and materials but rather at the general or prevailing prices for labor and materials, which, as a rule, can be deduced by taking the average or prevailing price for a term of years preceding the date of the valuation."

The writer agrees also that "an evident trend toward higher or lower prices" should be taken into account. It should not be forgotten that the valuation is being made with regard to the rates to be charged immediately in the future.

Page 20.—"Overhead Charges."—The writer wishes to endorse with all possible emphasis the opening statement of this section:

"When the items contained in the inventory are multiplied by the corresponding unit prices and the products are added, the result is only a part of the cost of creating the physical property, for the reason

Mr. Humphreys.

that the unit prices used are generally based upon the direct cost of similar works, and do not include the indirect or incidental expenses."

Again:

"In order to obtain the full cost of a building, it would be necessary to include the fees of architects, the amount paid inspectors, the cost of grading the grounds, the amounts expended for interest, taxes, insurance, and legal expenses, and a fair sum for the value of the time devoted by the owner to the planning and construction of the building."

Again:

"The allowance for overhead charges has generally been substantially under-estimated by commissions and the Courts, as well as by engineers of limited practical experience in construction work."

The fact is, as before suggested, the omission of overhead charges and liberal allowances for omissions and contingencies by some American engineers, even by some who have obtained high rank in the Profession, has tended to bring the Profession into disrepute with the hard-headed business men and bankers of the country—the men who have been taught by sad experience. This is unfair to the Profession, as a whole, but it is not hard to understand. It is time that the members of the Profession recognized that an engineer, to be a safe adviser, must be a commercial engineer, and so recognize that his work must successfully stand the test of producing an adequate return on the investment. Many an engineer who has had wide experience as a constructor, but who has had little or no experience as an operator and administrator, woefully fails to meet his responsibilities in this regard.

Page 21.—"Preliminary Expenses."—The writer concurs most fully in all that the Committee says under this head.

Page 23.—"Incidental Expenses During Construction."—The writer concurs practically in all that the Committee says under this head.

The examples given in the tables are instructive and convincing; many equally convincing examples could be cited from the writer's experience.

Page 26.—The writer does not agree with the Committee in its statement, as follows:

"but, under a continuous system of regulation, engineering for additions and extensions, if charged to current expenses, should not be included in the valuation."

There are many conditions to be considered before such a sweeping proposition can be accepted: What has been the rate of return? What were the conditions before the commission control went into effect? What has been the system of accounting prescribed by the commission, and so forth? It by no means follows, because a system of accounting and returns has been prescribed by a commission, that the system

thus prescribed represents in every instance the best practice or even good practice; no, nor even the facts as correctly and fairly interpreted. Mr. Humphreys.

Page 28.—The writer's experience fully confirms the Committee's recommendation that contingencies should be covered by a liberal allowance and then "even under such circumstances the actual cost is as likely to exceed as to run below the estimate." It is fortunate for the Profession that the Committee has covered this subject of contingencies in such detail, and so convincingly. The writer wishes to emphasize certain of the statements, as follows:

"Large contingent expenses are necessarily incurred in practically all important public works." After naming many causes for contingent expenses, the report goes on to say:

"Such contingent expenses * * * with the exception of the last two [slipping of earth or rock, and making changes in plans which increase cost], should be included as contingent expenses in any valuation of an existing property because the existence of the property does not give any clew to the amount of most of the contingent expenses involved in its creation."

Page 29.—The writer also agrees with the Committee that, whether the owner actually paid for insurance protection or whether he assumed the risk himself, there should be added "the sum necessary to insure its whole value against fire." He would add, also, all other liability or risk incurred.

He also agrees that there should be included in the valuation an adequate allowance for property "destroyed, reconstructed, or not used because of faulty design or construction," provided this is not due to negligence. It cannot fairly be assumed that the human agencies employed are infallible. It can be assumed, only, that the human agencies are up to the average in this regard.

Page 30.—*"Development Expenses."*—These expenses should be included, as recommended.

Page 31.—*"Working Capital."*—There should be no question as to the correctness of the Committee's position, stated as follows:

"Working capital is essential to the proper operation of a public service property and should be included in the valuation upon which fair returns are to be based."

To those who have not had experience with public service commissions and the witnesses who appear before these commissions against the corporations, this statement by the Committee may appear to be quite unnecessary; but the statement is not only true but most opportune. The corporations not infrequently have to meet the claim that a public service corporation can operate with little or no working capital.

Page 32.—*"Depreciation."*—Although the writer is in accord with certain of the isolated statements in the report in regard to "depreci-

Mr. Humphreys.

ation", he is completely out of accord with the Committee in its final conclusions on this all-important subject.

In the first paragraph: In cases where conditions require an annual allowance for "depreciation" (and they are in the majority), the writer agrees with the Committee that there should be included in the rates not only a sufficient but a liberal allowance to cover this accruing loss. He does not, however, agree with the Committee in its use in this connection of the term "amortize." Going to derivation, it can be traced, in the Latin, to *ad*, to, and *mors*, death. We can refer to three definitions:

1.—"In English law, to alienate in mortmain, that is, to sell to a corporation."

2.—"To kill; to destroy."

3.—"To apply to a debt for the purpose of extinction, as by a sinking-fund."

Although in discussing the subject of depreciation, it may be allowable and convenient to use the term "amortize" by way of illustration, it cannot safely be used in an exact way to describe the working of a reserve or sinking-fund to provide against the non-uniformity of annual cost of renewals of plant. To "amortize" should convey the meaning that the investment is to be finally retired by the amortization; but such is wide of the facts, as the writer hopes to show. A municipality should amortize a bond issue which must be retired at a given date, and has been issued to finance a disappearing asset; or a capitalized leasehold; or capitalized standing timber; or mining properties. In all except the first of these cases the investment is day by day being extinguished or liquidated. In the case of a public service plant, day by day the several dates are approaching when its parts must be renewed so that the service may be continued. The investment is not extinguished, but is only given a different form.

Page 32.—Second Paragraph.—The writer completely disagrees with the Committee's statement, as follows:

"A depreciation allowance is, in effect, a payment from the ratepayer to the corporation of a part of its investment, and such part of the investment as has thus been repaid should not appear in subsequent valuations of the property."

The report is not consistent on this point. For instance, on page 18 of the additional statement, it is said that "it would obviously be confiscatory if the value in such cases were to be depreciated." The cases referred to are the Replacement Method and the Sinking-Fund Method of computing a "depreciation" allowance. As thus computed, these are "depreciation" allowances, and therefore, according to the report, as above quoted, they should be regarded as a repayment of

investment "and should not appear in subsequent valuations of the property." Mr. Humphreys.

The Committee then goes on to say:

"It is necessary to adopt some practicable and equitable method of determining depreciation allowances which will meet the following requirements:

"1. The method should be one which will insure, with as much certainty as possible, payments to the corporation to amortize the various items of property when they cease to have value.

"2. It should so adjust the annual depreciation allowances as to distribute the burden as equally as practicable among the rate-payers of different years."

Referring to Requirement 1, the writer does not agree with the Committee, if the report means that the "payments to the corporation" amortize the investment.

Referring to Requirement 2, the writer agrees with the Committee, if the report means that the cost of all maintenance of plant should, by proper accountancy methods, be spread as uniformly as possible over the years during which the several parts of plant are to be operated in the service of the rate-payers; but it is difficult to see how this reading can find support in Columns 3 and 7 of the table on page 34.

In the writer's opinion, it is most unfortunate that the term "depreciation" has been used, as it has come to be used, to stand for the cost of deferred renewals of parts of plant as rendered necessary by physical decay (or wearing out to a point where no longer efficient and economical), or obsolescence, or inadequacy. If the subject is considered broadly, these deferred renewals, together with repairs and current renewals, may all be included under a single term, such as maintenance. Certainly we are not warranted in thinking that the money spent for repairs and current renewals is "in effect a payment from the rate-payer to the corporation of a part of its investment." If thus considered, then certainly it must be admitted that the money thus repaid to the corporation is at once re-invested by the corporation for the service-benefit of the rate-payer through the current expenditures for the up-keep of the property. If this is true of the repairs and current renewals, it is equally true of the deferred renewals, namely, "depreciation."

To make this point plainer, consider more in detail the reason for a "depreciation" allowance. Certain large payments have to be made from time to time for the renewal or replacement of certain more or less costly items of plant having a more or less extended life. If no thought were given to the subject, no provision as to accounting for, or financing, this loss would be made, and the cost of renewals or replacements probably could not be met from the income of the year when made, unless, possibly, return on capital were for the time defaulted. Furthermore, if in other years no provision were made in

Mr. Humphreys.

the Loss and Gain Account for this accruing liability, the yearly statements of profits would be inflated.

Now this, in a measure, is what did occur in many instances in past years, and particularly before the days of public service commissions. The conservative managers recognized these dangers, in a general way, and so they reserved part of their earnings, more particularly in good years, against the reduced earnings in "lean years." Certain of the ultra-conservative owners took advantage of good years to charge to loss and gain account and credit to plant account, or other asset accounts, large lump sums against "depreciation." The amounts thus written off were determined by the character of the year's business—extra fat or extra lean—and by the temperament of the controlling spirits in the board of directors, rather than by any attempt at accurate estimate or computation. Frequently, the very payments which had been anticipated in these periodic credits to plant account, namely, the expenditures for renewals or replacements, when actually made were debited again to loss and gain account, thus reducing the debit balance of plant account to a lower and lower percentage of the actual cost of plant. Where such credits had been made to plant account (or any property account) in anticipation of renewals later to be made, when those contemplated renewals were made, the expenditures therefor should have been charged to the plant account. The fact that, in some cases—perhaps too many cases—instead of this ultra-conservative practice, exactly the opposite course was followed, with the result that plant account became inflated, does not change the record as to the great majority of the public service corporations. Referring to the ultra-conservative practice, it is because so much of income was expended for extensions and improvements, which might have been legitimately distributed as return on investment, that the legitimate opportunities have been afforded for increasing the capitalization in connection with changes in ownership. It is also true that, in some cases, though in far less number than is popularly believed, this opportunity has been worked past the legitimate limit, resulting in "watered" securities. Many millions of dollars of "water" in securities have been eliminated by the investment of legitimate earnings otherwise applicable to dividends.

Many a public service corporation in the United States, if fairly valued, would now show a total far in excess of its total capital securities. Particularly is it true of many of our railroads, that they cannot earn 6% on a conservative valuation of their properties.

Now that the public service corporations are subject to regulation, especially as to rates, no such loose methods of accounting can safely be followed, and so plant account, or any property account, should not be written down on the basis of estimated future loss. Such losses should be covered by setting up reserve or liability accounts subject to

Mr. Humphreys.

correction to cover these estimated accruing losses. It should be understood that all expenditures to cover items which have been included in the estimate of accruing losses and contingencies, particularly renewals of plant, should be debited to the proper reserve or liability account. The writer's excuse for again emphasizing this point is the fact that not a few of those who discuss "depreciation" most glibly, assume that the corporations intend to debit these expenditures when made to loss and gain account and thus allow the reserve to go on accumulating indefinitely. If it is once understood why a "Depreciation Reserve" is established, it must follow that this is necessarily a credit and debit account.

If the debit to loss and gain account to cover estimated "depreciation" is made as a credit to a property account, instead of to a reserve account, we give, to those who are seeking an opportunity to confiscate investments, an opening to claim that debits to loss and gain, which in common prudence we have established to meet renewals and all contingent losses, are actual, present, and final lowerings of property values. Nothing could be farther from the true and legitimate theory of an annual allowance for accruing "depreciation," or still more, for contingencies.

Suppose, for instance, that we could in some way be insured against all yearly fluctuations in the cost of plant renewals, losses by uncollectable bills, liability for accidents, increase in cost of raw material, or labor, etc., then we could submit to a rate which contained no allowance for "depreciation" and contingencies, and there would be no opportunity for the Committee to report in favor of deducting accrued theoretical "depreciation" from plant valuation.

Now, in certain cases, and up to a certain point, such uniformity of annual charges for renewals can be found. In the case of a corporation having many plants, widely scattered, built at different times, the annual expenditures for renewals as a whole will tend toward uniformity. Here we have a case of averages. Certainly, in such a case, so far as the "depreciation" is covered by these annual expenditures, there should be no claim for allowance, and so no deduction from plant valuation because of theoretical accruing "depreciation;" and this because the accruing "depreciation", considered as a whole, is met by the annual expenditures for renewals. Why, then, should such deduction be made simply because these charges for renewals lack this uniformity of character? There is no fair reason, in the case of non-uniformity of annual expenditures for deferred renewals, why such deduction should be even temporarily made from investment, as shown in plant account, while the "depreciation" allowance by the Sinking-Fund Method is building itself up by its own interest accretions against the days of renewals. Naturally, under the conditions here assumed, analyses of the accounts and of the operations and estimates and com-

Mr. Humphreys.

putations would be necessary, to demonstrate the fact that the amount thus annually expended did equal the average cost of all renewals.

Where, in the writer's opinion, the Committee falls into error is in treating the "depreciation" allowance as if it were to pay for plant which is to go out of existence and hence the investment is to be extinguished, as far as the investor is concerned. This is quite at variance with the fact; for, though the particular part of plant which is being renewed or replaced does go out of existence, or is sold for service elsewhere, or as junk, there is another part of plant put in its place; and frequently a better part of plant, a part more up to date and hence more efficient and economical, and consequently more valuable from the standpoint both of the rate-payer and the corporation.

Page 34.—Having thus most briefly discussed the accountancy of "depreciation"—a phase of the subject to which, as it appears to the writer, the Committee has given insufficient attention—specific reference will be made to the Committee's "Equal-Annual-Payment Method of Computing Depreciation," as illustrated in the table under that heading and as discussed in the pages following.

Some of the explanations accompanying the table will be quoted:

Page 35.—

"The depreciation during each year, as given in Column 3 of the table, is exactly the same as if computed by the so-called Sinking-Fund Method; that is, it is the constant annual payment to a sinking fund added to the year's interest on the accumulated fund at the beginning of the year."

* * * * * * *

"Although the Sinking-Fund and Equal-Annual-Payment Methods, under the assumptions made, provide for the same annual rates, there is a difference in the principle involved. The Sinking-Fund Method provides for a uniform annual payment to the sinking fund which must be invested and earn interest in order that the accumulations may amount to the full value of the item of property at the end of its life, while the yearly depreciation allowances by the Equal-Annual-Payment Method include sums equivalent to the interest in the Sinking-Fund Method and therefore amount without interest to such full value."

These two statements must be considered together carefully. According to the report, these two methods are the same, and they are not the same. On the surface it would appear that the accumulation at any one time during the expected life would be the same; but if the equal-annual-payments are compounded in the same way as the sinking-fund payments, the total at the end of the 20 years will be found to be very different. In the case of the Equal-Annual-Payment Method, the total will be $152.83, instead of $100 by the Sinking-Fund Method. This is shown by the explanation of the Committee as quoted, for it is stated that the equal-annual-payment "is the constant annual pay-

ment to a sinking fund added to the year's interest on the accumulated fund at the beginning of each year." Mr. Humphreys.

The first of these two statements seems to warrant the assumption that the Committee claims that the "depreciation", as found at any time during the expected life by either the Sinking-Fund Method, as it really operates, or by the Equal-Annual-Payment Method, as illustrated in the table (and, therefore, excluding interest), is the accrued theoretical depreciation. In many other places in the report the Committee appears to support the same claim. This is not a fact, except at the very end of the expected life, and then only if the correct assumption has been made as to expected life. With the Sinking-Fund Method, at any time up to the end of the last year, necessarily the accumulations will not equal the estimated depreciation, for the very reason that the compounding of interest must be allowed to operate to the very end of the life to secure the necessary total accumulation. If the values are accepted as found in Column 2 of the table on page 34, "Value at end of year", at the end of 10 years the value of the plant, which cost new $100, is shown to be $61.96; whereas, by a uniform distribution of theoretical or "latent" depreciation, the value would be only $50. This shows that, if the Committee hopes to prove that its deduction for depreciation will always equal the accrued liability due to age, its own table proves to the contrary, and lays it open to criticism. (The writer will refer to this point later, in connection with remarks on commission and Court decisions.)

The only way in which such a claim could be supported would be by proving or assuming that "depreciation" increases year by year, as indicated in the table. Nothing of this kind can be proved. Quite apart from considerations of obsolescence and inadequacy, there is no law capable of general application by which one can measure accurately in advance the variations in the rate of actual depreciation of a plant composed of many parts varying widely in character.

If we confine ourselves to Columns 2, 3, 4, and 6, namely 5% sinking-fund computation and 5% return on investment, how do we find that this constant annual "Combined Depreciation and Return upon Investment" is secured? Simply by increasing arbitrarily the rate of depreciation allowance from $3.02 for the first year to $7.64 for the last year.

Of course, there is no such increase, in fact, in the depreciation in a well-managed public utility. Here, we must always remember, we are referring to the same item of property and are not considering extraordinary happenings or contingencies. If the latter are considered, no law can be established, and hence the rate assumed must be subject to modification, to meet changes in conditions as they develop.

Now consider for a moment the basis for using a sinking-fund rate to cover depreciation.

Mr. Humphreys.

The basis for this method is that if the part of plant is not to be renewed until 20 years have passed (to follow the Committee's table on page 34), then, though the loss has to be provided for annually in the rates, the actual payment is deferred, and so, if the *pro rata* amount is to be taken out of income each year, it can rightly be assumed that these advance payments should earn interest until the day they come due. If we place this money out at interest, an annual payment of 3.02% will accumulate to the required 100% at the end of 20 years, provided we can secure a compound interest rate of 5%; an assumption not warranted in practice.

Column 3 of the table, though footing up only $100, if compounded at 5%, as already stated, will produce a total of $152.83, which is the same as 20 payments of $7.64. It is to be noted that if we set aside $5 a year, the full amount required for the Straight-Line Method, and allow these amounts to compound at 5%, the sum will be $165.47, or only $12.64 more than the sum obtained by compounding the equal-annual-payment allowances.

If the 7% depreciation sinking-fund rate is used, as favored in Mr. Stearns' supplementary statement, the compounding of the depreciation allowances will produce $176 at the end of the 20 years, instead of the required $100. If the straight-line payments of $5 are compounded at 7%, they will produce $205.

In passing, it may be noted that, in Mr. Stearns' supplemental report, and in Mr. Snow's statement, in the case of a 7% return on investment, the annual combined payment is made to appear more like an "equal-annual-payment" by the assumption of a sinking-fund rate of 7 per cent. Of course, if the sinking-fund rate and rate of return are assumed as equal, this uniformity can be shown, provided the same arbitrary assumption is made as to the increase in the rate of depreciation year by year, as before discussed. The writer presumes it will be conceded that, in the operation of public utilities, the establishment of a sinking-fund outside the business is so rare as to be practically negligible when we are considering methods to be actually used.

The Sinking-Fund Method, however, cannot be ignored, because it does offer a process by which the annual loss due to depreciation can be provided for theoretically. The writer says "theoretically," when perhaps he should any "hypothetically", for no estimate on accruing "depreciation" can be depended on as to accuracy. Here is one of the dangers of the Committee's report, for the layman reading it might easily be led to believe that "depreciation" allowance is a quantity to be mathematically determined in advance. There is justification in making ample allowance for the safety of the undertaking, and this in the interest of rate-payer as well as owner. There is justification, also, in establishing a reserve against operating contingencies, outside of and beyond the factors usually included in a "depreciation" estimate. This

Mr. Humphreys.

reserve is subject to revision year by year by the commission in control, and if the reserve is not treated as a surplus, and is kept within reasonable limits, no injustice can result to the rate-payer.

If, then, we are placed in the position where theoretical or estimated depreciation can be met by a sinking-fund payment, there is an apparent reason why our annual allowance should be limited to that amount. We can claim a still larger amount if all contingencies are included; and here may be found a practical justification even for an allowance based on the Straight-Line Method.

In the table on page 34 the Committee has computed:

"the depreciation each year * * * by the so-called Sinking-Fund Method."

* * * * * * *

"Although the Sinking-Fund and Equal-Annual-Payment Methods, under the assumptions made, provide for the same annual rates, there is a difference in the principle involved * * * the yearly depreciation allowances by the Equal-Annual-Payment Method include sums equivalent to the interest in the Sinking-Fund Method and therefore amount without interest to such full value."

In other words, year by year the amount charged against the rate-payer increases from 3.02% until it is 7.64%, and, by reason of this increase, for which there is no warrant in actual conditions, the Committee is willing to deduct accrued depreciation from the reproduction-cost-new. The fact remains that the combined depreciation allowance and rate on the investment remains 8.02% each year, only if the required arbitrary assumptions are made as to the two rates being equal. With the assumptions made there is no difficulty in computing correctly the table on page 34.

If the same conditions are maintained for the 20 years, as shown for the first year of the table, the rate-payer pays 8.02% on the $100, and he pays no less when "depreciation" is deducted by the Committee's method.

It is proposed that we shall say:

"If you wish to deduct for depreciation in the valuation, you can do so provided you allow us to increase correspondingly year by year the allowance for depreciation."

For instance: For the twentieth year of our table we will accept a return of 5% on only $7.64 instead of on $100, or 0.38% instead of 5% on $100, provided you grant us an allowance for depreciation of $7.64 instead of the required $3.02.

But let us look a little further into this "constant each year" claim. On page 7 of the report, we read:

"Justice and equity require that in any regulation of rates fixing the amount which may be earned by a public service corporation there shall be taken into consideration two distinct features.

Mr. Humphreys.

"First, the annual return covering interest and profit, to which the corporation is entitled for the use of its capital, having in view the risks incidental to the investment."

In view of the happenings of the last few years, the writer presumes that the Committee would hardly claim that 5% is a fair return for "interest and profit * * * having in view the risks incidental to the investment."

Apparently, the Committee and the writer should be in accord in regarding 5% as inadequate to cover "interest and profit", for on page 36 we read:

"The foregoing statements [table on page 34] have been based on the use of 5% in all computations, but there are reasons, to be referred to subsequently, why the rate of return for the use of capital will generally be larger than the interest rate used in computing depreciation, and when there is such a difference in the rate, the combined annual depreciation and return for the use of capital, as given in Column 7 of the table, will not be strictly uniform from the beginning to the end of the twenty-year period."

The Committee would have been much nearer to the truth if the word "strictly" as qualifying the word "uniform" had been omitted.

Page 36.—Referring to the table on page 34, the report says:

"It has already been stated that in preparing the table only two of the three factors were taken into account, and the introduction of the third factor—the cost of repairs and operation—will affect the degree of uniformity because as a rule such cost increases as the property grows older. The inclusion of such cost, therefore, will increase the quantities in Columns 6 and 7 to a greater extent in the later than in the earlier years, making the results based on Column 6 somewhat greater in the later years than in the earlier years, and those based on Column 7, under most circumstances, more nearly uniform than they are in the table."

Referring to the table, it is found that the uniformity of the "Combined Depreciation and Return upon Investment", as given in Column 6, namely, $8.02 for each year, is sadly lacking in the quantities given in Column 7. In this last column the combined result is based on 5% sinking fund and 7% return on investment, instead of 5% and 5% for the uniform result of $8.02.

First, let it be noted that if this increase in "Cost of repairs and operation" operates to make the quantities in Column 7 more uniform, it operates to make the hitherto uniform results in Column 6 less uniform.

Referring to Column 7 (7% return) it is found that the combined payment for the first year is $10.02 and for the twentieth year is $8.17, a difference of 1.85 per cent.

Now, as to the compensating effect as claimed; namely, that "cost of repairs and operation * * * as a rule * * * increases as the property grows older."

Mr. Humphreys.

This depends on the design, construction, and operation of the plant, and particularly on the care and intelligence with which it is maintained and renewed. The result might easily be the opposite of that affirmed by the Committee; but here we must not forget the results shown in Column 3 of the table—"Depreciation during year". This is computed on the basis of a 5% sinking fund.

The results run from $3.02 for the first year to $7.64 for the twentieth year, or an increase of 150 per cent. There is no warrant in fact for any such increase in the "depreciation", but, such an increase having been claimed, there certainly remains no room for a further increase in "the cost of repairs and operation * * * as the property grows older."

Even as to "depreciation" (liability for deferred renewals), the rate at which this accrues is most problematical. Sometimes, and in some cases, this no doubt follows a straight line; sometimes it follows a most eccentric curve. If we attempt to base an estimate on the rate at which this item of loss actually accrues within the assumed life period, we shall involve ourselves in confusion worse confounded; particularly is this true if to the "depreciation", which includes obsolescence and inadequacy, we add all other contingencies. The most we can do is to make a conservative estimate as to the expected life of the many items of plant, so arrive at an average, and on these assumptions make a liberal allowance for the periodic renewals of plant and all contingencies. Having made this estimate as to the loss to accrue through a given number of years, conservative accounting and conservative financing suggest that this loss should be spread uniformly over the years, or *pro rata* on the present service and the prospective service, as estimated to the best of our ability.

Even though we could foretell exactly the rate from year to year at which this "depreciation" loss was to accrue, there would be no value in the information. Here the writer is not referring to the life of the parts, but to the rate at which the "depreciation" accrues within the assumed life limits.

If it were not for the practical need for spreading this loss *pro rata*, there would be no adequate argument to support a claim for annual allowance for "depreciation." This feature of the system of accounting (for that is what it is) may be vital for the protection of the investment, and particularly must be so where there are involved items of plant of large cost and long life.

One thing we can be sure of: these estimates never will be absolutely correct. In any specific case no final reliance should be placed on experience tables. These tables may be helpful in the hands of those qualified by personal experience to make the proper adjustments, taking into account design, construction, operation, methods of accounting, etc., and all through actual examination. The academic

Mr. Humphreys.

statistician, in the absence of personal needful experience, finds in these tables a fruitful source of information to be misapplied in developing any proposition he is for the moment supporting.

This question as to the propriety of introducing factor number three is suggested also by a statement on page 72 of the report, namely: "Depreciation allowances are credited to the capital account, and not distributed as dividends, and replacements become charges against capital." Here, again, how shall we draw the line between minor and major renewals or replacements?

On the other hand, if we charge to "repairs" all repairs and minor renewals paid for currently, and include in the estimate to cover "depreciation" only the major renewals not covered under "repairs", crediting the "depreciation allowance to a reserve account and charging to that account all expenditures contemplated in the estimate to cover "depreciation", there is thus presented the least opportunity for confusion or for unwarranted interference with the fixed capital accounts.

Again, referring to Column 5, the return on the undepreciated investment is found to be 7% for the first year and 0.53% for the last year. The total for the 20 years is 84.65%, or an average of 4.23 per cent.

Again, referring for support to page 7 of the report, even 7% might not be a fair return or an adequate return in many cases.

As the rate of return is increased, it becomes more and more apparent that the "Combined Depreciation and Return upon Investment", "will not be strictly uniform."

Referring to the table on page 34, and adding thereto to cover return on investment of 8%, 9% and 10%, it is found that the "Combined Depreciation and Return upon Investment" shows a variation (non-uniformity) between the first and twentieth years as given in Table 32.

TABLE 32.

Return Percentage.	Combined Depreciation and Return.		
	First year.	20th year.	Difference.
5	8.02	8.02	0.00
7	10.02	8.17	1.85
8	11.02	8.25	2.77
9	12.02	8.33	3.69
10	13.02	8.40	4.62

(Note.—Twentieth year, $7.64 \times 1.08 = 8.25$, $7.64 \times 1.09 = 8.33$, $7.64 \times 1.10 = 8.40$.)

Thus the table itself, when analyzed and expanded to cover other and legitimate rates of return, fails to support the report as to uniformity of annual payments. It is also found that, for the last year of the period, this Equal-Annual-Payment Method, for an increase

Mr. Humphreys.

of from 5 to 10% in the rate of return gives an increase of only (8.40 — 8.02) = 0.38% for "combined depreciation and return upon investment." Therefore it is found that this "uniformity" of the Equal-Annual-Payment Method depends for its "uniformity" on a rate of "annual return covering interest and profit" (page 7) which even the avowed enemies of the public utilities would hesitate to attempt to justify.

There is nothing to be found in the report, or in fact, which tends to make uniform either in rate or amount the annual expenditures for "repairs and operation" and deferred renewals. We can provide for uniformity of dividends by correct accounting methods, and by the building up of a reserve. As a general proposition, there is no way to make the total annual expenditures uniform.

If the Committee is looking for a constant return on the continuing investment, it has completely failed, as shown by Column 4 of the table on page 34.

But why involve "depreciation" with rate of return? There is no more reason why maintenance (of which "depreciation" is an element) should be thus involved in the effort to produce a constant quantity, than labor, coal, taxes, or any other expense item.

Here we are reminded that some statisticians and accountants differentiate between taxes and other items of expense; though taxes are no less an expense of operation because they go to the support of the several branches of government. Dr. Webber, the Chief Statistician of the New York Public Service Commission, First District, on a notable occasion deducted the amount paid out for taxes in connection with the computation of the cost per thousand for gas.

Consider for a moment the application of the Committee's method, as illustrated in the table on page 34, to the usual practice of investing "depreciation" allowance in plant extensions. If we invest $3.02 in our own business, that $3.02 thus invested each year must produce the 100% at the end of the 20 years. These extensions might be considered as carried into a development apart from the property as a whole. The earnings from these segregated investments would then have to produce sufficient gross earnings to pay for their own "depreciation" and also produce a net return which would meet the sinking-fund requirement of the original plant investment. If this method were applied to the "depreciation" reserve, as the property developed, the problem of keeping the earnings segregated so as to maintain on our books the many sinking funds thus required would present complications in the accounting department practically impossible to meet. Instead, therefore, of establishing these sinking funds on our books by segregating the earnings produced by the plant extensions paid for from the several "depreciation" allowances, the practical way is to consolidate all the earnings and compute the "depreciation" allow-

Mr. Humphreys.

ance on the total investment in depreciable property (or rather, such depreciable property as is included in our deferred renewal scheme) at the end of each year. This is not, as has been charged, asking for a return to the owners on the sinking fund as well as on the original investment, because we are computing the "Depreciation" allowance on the sinking-fund basis, and so the earnings from plant built from the "depreciation" fund should provide the interest necessary under the Sinking-Fund Method to produce the 100% required for renewals. This the owners must guarantee as trustees of the fund, if they invest in extensions. If the interest accumulations exceed the required amount, as should be the case, the owners are entitled to the excess because they have assumed the risk as guarantors.

On the other hand, plant extensions are not infrequently made in advance of a remunerative demand for service, and so, in this case, the return on these "depreciation" reserve investments may be less than the average rate of return on the investment as a whole.

The writer has shown that, by the Sinking-Fund Method, even when applied to investments in extensions of plant, 8.02% will cover "depreciation" and return on investment, if we assume 5% in each case. Now, the report specifically states that "depreciation" should not be deducted in the case of the Sinking-Fund Method. Mr. Stearns confirms this on page 18 of his supplementary statement, and says that thus to deduct from the value new "would obviously be confiscatory." Now, if the amount to be charged to the rate-payer in the two cases is exactly the same, why is it right in principle to deduct for depreciation in the one case and not in the other?

The writer quite understands that the Committee provides for deducting for "depreciation" by shifting the burden of the rate-payers from return on investment to "depreciation" allowance; but this is only an arbitrary rearrangement of the numbers between Columns 3 and 4. This increase in rate to be charged for "depreciation" allowance has no basis in the conditions met in practice. If the principle of the Sinking-Fund Method is appealed to, to obtain a basis for the first payment of $3.02, there is no reason why the same principle should not govern to the end of the assumed life of the plant.

Just so sure as engineers admit that "depreciation" (cost of deferred renewals) can be thus deducted from cost new, just so sure "depreciation" will be deducted irrespective of the methods of computation used.

No adroit tabulation of quantities based on arbitrary assumptions will serve to save us from the dangers to which this feature of the Committee's report must subject us.

As testified to by Commissioner Maltbie in the Bucyrus case, the New York Public Service Commission of the First District deducts for "depreciation" on the straight-line basis. Then, in a case before

Mr. Humphreys.

that Commission, for the tenth year, as shown by the table on page 34, 50% would be deducted instead of the 38.04% shown by the Committee in Column 2.

One thing cannot be lost sight of safely: this subject of "depreciation" is not easily understood. This fact is demonstrated by this report and the discussions thereon; and this quite apart from the question: who is right and who is wrong?

This being the case with the engineers and operators of experience, we certainly cannot expect the commissions and Courts to understand the subject readily, even though all the commissioners and all the judges may be keen to learn the truth through the desire to hold the scales of justice evenly.

Experience, however, does not teach us that all these officials are keen to do exact and even justice. On the contrary, acting under the influence of their advisers, many of whom treat this subject most academically; they have already in not a few cases shown a marked disposition to decide against the investor when a plausible reason could be found for doing so.

The commission and Court decisions on this question are found to be conflicting when carefully analyzed; and this is easily understood when we see how inadequately the subject of depreciation has generally been presented by the witnesses.

It is, then, our duty, as men charged with a very special and grave responsibility, to be prepared to place before the commissions and Courts this subject of "depreciation" and all involved questions in the simplest possible form.

Here the writer may appropriately quote from an address delivered in March, 1914, before the American Railway Engineers Association of Chicago by Judge C. A. Prouty, formerly of the Interstate Commerce Commission and now Director of Railway Valuations:

"In the last fifteen years the price of every article of universal and general consumption, with one exception, has advanced, and that exception is transportation by rail. If transportation by rail alone has not advanced it is because railway engineers, by providing a better way and a better machine to operate upon that way, have rendered it possible to make economies which have offset the increased cost of labor and of supplies. The United States is about to enter upon a work of very great consequence, and the railway engineers are identified with that work. The problem is not altogether an engineering problem. It smacks of economics and of law and of politics, but the business of ascertaining and collecting a great part of the information is peculiarly a task of the engineer's, and I am not certain but the engineer may finally turn out to be the best qualified of all to consider the other problems.

"Now, when I began this work I was told that an engineer could measure and figure with accuracy, but that he was not competent to discuss the intricate problems presented by the valuation of our rail-

Mr. Humphreys.

roads, and that we must be very careful not to let him undertake to discuss them. I am fast coming to the conclusion that he may be better qualified than anybody else to discuss them. I have been a lawyer all my life and I believe that my profession is the greatest of all professions, but I am obliged to admit, and I think I have said this before, that the training of a lawyer does not fit him for the discussion of questions of this kind. A lawyer by his training is a partisan. If you go back to the law school you will find that he is given a certain thing to affirm, and it is his business to make out that case. In life he has one side of a controversy, and he must establish that his side is right.

"The engineer is entirely different. He begins in school with mathematics. There is but one answer to a problem in mathematics. It may be hard work to find it, but there never can be two answers. When the engineer gets into life it is still his business to find the fact, and just according as he can find the fact and be certain of the fact, he grows. If an engineer designs a bridge, and that bridge falls, his reputation falls with it. He cannot call in the undertaker and bury his blunder, as the doctor does. He can't charge it to the stupidity of a court, as the lawyer does. He must assume the burden of it himself. So I say that the very training of the engineer fits him for that precise kind of thinking which is essential in the working out of these new problems where absolute impartiality is necessary."

Here at the outset it should be kept constantly in mind that the annual allowance for "depreciation" is not susceptible of being determined with mathematical accuracy. This, it is presumed, every member of the Society, who has had a long and wide operating experience and has profited thereby, is willing to concede.

The depreciation allowance is based on an assumed life for each part. Referring to the table on page 34, let us suppose the life of the part of plant under consideration, or the time for renewal, extends to 21 years. This would be an unusually close approach to the estimate. Then, as at the end of the twentieth year the total cost has been deducted through the depreciation allowance, for the twenty-first year there will remain no investment on which to claim a return, and no ground for claiming a depreciation allowance. Hence, there will be no ground for claiming that the service rate shall include a return on the investment and a depreciation allowance; and this condition would continue until the plant was actually renewed.

This indicates that the so-called Equal-Annual-Payment Method is bound rigidly to its expectation-of-life estimate; whereas, the Sinking-Fund and Straight-Line estimates as generally made are subject to correction year by year.

What is plain to the engineer, however, may not be plain to the layman. May the writer repeat the suggestion, that the laymen who read this report will almost to a man receive the impression that the allowance for "depreciation" is a quantity which can be determined

accurately in advance of the established facts, and that the Committee favors deducting from "depreciation". Mr. Humphreys.

Even in a case where the layman might be inclined to think that a readjustment was in order, it should still be borne in mind that an apparent excess in the reserve might be justified by the chances, always more or less probable, of extraordinary happenings beyond the power of mortal to foresee or provide against, except through such a reserve. Those, at least, who have had any wide experience in the operation of public utilities must be in a position to know that such operating contingencies (quite apart from the contingencies connected with the construction period) cannot be disregarded safely.

Page 39.—"Straight-Line Method."—The report states that this method "assumes that the value of the item of property under consideration decreases an equal amount in each year of its life" and therefore (page 40) "it is inequitable as it makes a much greater demand on the rate-payers of the earlier years than on those of later years."

The writer is unable to agree with the Committee as to either of these statements.

Neither the Straight-Line Method nor the Sinking-Fund Method necessarily assumes anything as to the actual rate of depreciation, but, as a scheme of accounting, each of these methods endeavors to place an equal annual burden on the years of the expected or assumed life.

Instead of placing an equal annual burden on the years the burden could be spread *pro rata* upon the sales of service; this would require an assumption as to any expected change in the annual sales of service. This change in method of distributing the burden has no bearing on the question of deducting for "depreciation."

If the cost of deferred renewals ("depreciation") is treated as an item of cost or expense, it is at once seen that either the Straight-Line Method or the Sinking-Fund Method is more "uniform" as to burden than the Committee's "Equal-Annual-Payment" Method.

As before stated, there is no more reason why the deferred or periodic renewals ("depreciation") should not be considered an item of operating cost than that repairs and current renewals should not be thus considered. Broadly considered, repairs and all renewals are included in the cost of maintenance. In fact, not a few accountants cover all maintenance as above described by an estimated annual allowance, carrying this periodically into a Reserve Account as a total and then debiting against the credit balance thus created the actual payments for repairs and current renewals as well as deferred or periodic renewals. The intention or hope is that by thus combining in one estimate repairs and all renewals the annual charge for all maintenance can be kept more nearly uniform.

Mr. Humphreys.

Under such a system as this, how would the Committee support its claim for deduction of depreciation? If part of the credit balance of this inclusive reserve happened to be applicable to repairs and minor renewals, would the Committee also deduct therefor?

If so, to be consistent, they should also deduct for repairs and minor renewals as currently debited direct to loss and gain where the total is found to be below the annual average—namely, indicating an accrued liability for repairs.

The writer is willing to admit that the Straight-Line Method is open to criticism, but not for the reasons given in the report. This method calls for the advance payment of the loss due to prospective renewals, whereas it can be claimed on behalf of the rate-payer that these annual allowances should be permitted to earn interest until the days come to pay for the renewals, thus reducing the allowance to an annuity basis. Even then, however, the Straight-Line Method is not as unfair as it may at first seem. It is to the interest of the rate-payer as well as the owner that all accruing losses and all contingencies should be provided for liberally. On page 70 of the report we find a statement which appears to support this position, as follows: "A good sized surplus is desirable for preventing frequent changes in rates and dividends, and for protecting stable conditions." The writer prefers to regard this accumulation as a reserve rather than a surplus, especially as being fairer to the rate-payer. Governmental control of gas companies in Great Britain, without directly authorizing an allowance for "depreciation", thus provides through insurance reserves for the distributing of all accruing losses (including "depreciation") over the years, and also provides for changes in prices of supplies and materials and rates of wages, thus insuring stability of dividend rates and so making these public utility securities more desirable for trust investments. Evidently, the true significance of "depreciation" is better understood by the authorities in Great Britain than by those in the United States.

If by the Straight-Line or any other method, the reserve is found to be accumulating in excess of the apparent need, all things considered, including stability, the scheme is open to revision.

And this is where the Commissions should exercise their powers, always provided they are sure of the ground; but, commission or no commission, no estimate to cover accruing "depreciation" should be allowed to stand year after year without question. Such an estimate should always be open to revision in the light of changed conditions and increased experience. Nothing, to the writer's mind, is less defensible than the setting up of a "depreciation" scheme by rules and tables, to be from then on regarded as sacrosanct.

Before we can decide that the reserve is too large, we must, however, take into account contingencies, and not govern ourselves entirely by

the things in view or even in mind. Here is another reason why a straight-line allowance should not be condemned hastily. Mr. Humphreys.

Let us for a moment consider what would be the result of a straight-line allowance, provided the estimates were by chance found to be actually accurate. Let us see what the Straight-Line Method would provide in the way of return of the investment to the owner in addition to providing for "depreciation."

Referring to the tables on pages 34 and 40, the straight-line annual allowance would be $100 \div 20 = 5$ per cent. The amount required by the Sinking-Fund Method would be 3.02 per cent. The difference or excess is 1.98 per cent. This 1.98% also might be allowed to accumulate at compound interest at 5 per cent. At the end of 20 years this would amount to $65.47.

Thus, by the "Straight-Line" Method, assuming that the life expectation had not been over-estimated, and assuming a return on the full 100% of the investment each year (as differentiated from the Equal-Annual-Payment Method), after providing for deferred renewals, $65.47 of the investment would be returned to the owners, but with no reserve remaining for contingent happenings.

Page 41.—"Actual Inspection Method."—The writer is unable to find any ground for the following statement in the report:

"This method does not take account, to any considerable extent, of functional depreciation, and the great injustice which may be done a corporation by the failure to take such depreciation into account has already been stated."

It is because the writer wants to provide as completely as possible against the "great injustice" referred to that he here differs from the report.

There is no reason why the valuation of property by actual inspection should not take full account of all the elements included in "depreciation." Through actual inspection by competent experts, the probably remaining useful life, having in mind physical decay, obsolescence, and inadequacy, can be determined much more accurately than by reference to tables as used in the making of an estimate perhaps years before the making of the appraisal. Backsight is certainly more to be relied on than foresight. An appraisal without competent inspection would be valueless.

The report itself says that such actual inspection should be made (page 42) "partly for the purpose of determining the probable future life of the various items of property."

Page 42.—"Replacement Method."—There is no good reason why this method, in certain cases, properly applied, should "hold back from the corporation an annual sum for depreciation."

If the current annual expenditures for replacements do not provide for the average annual cost of such renewals, including all elements of

Mr. Humphreys.

"depreciation" (and, as a rule, they do not so provide), the corporation is entitled to an allowance therefor to be included in its total of annual cost of service; and this, as before stated, is simply to spread this loss or cost item as uniformly as possible over the years of service. The best way to insure the granting of such allowance is to educate the commissions and Courts as to the real significance of "depreciation."

Page 42.—"Application of Equal-Annual-Payment Method."—As before suggested, in establishing a scheme on which to base an annual allowance for "depreciation", the line then must be drawn between the classes of items which are to be charged directly to operating cost through "repairs" or some equivalent account, and the classes of items which by journal entries are to be debited to operating cost and credited to reserve. When these latter items of deferred renewal are actually paid for, the debit, of course, is to be made against this reserve. Thus the balance is maintained and we are constantly afforded opportunities to check up our estimates on "depreciation" through the facts as they develop. By crediting "depreciation" allowance direct to plant account, no such segregation of the items going to make up the average annual cost of renewals is available.

The last paragraph of this section is as follows:

"Under a continuous system of accounting, small items of property purchased and charged directly to current expenses should obviously not be included in the valuation of the property upon which the annual return is to be based."

There are many reasons why this is not "obvious". How are these items to be located with any degree of exactness?

Suppose, in the estimate for "depreciation" allowance, it is assumed that such "small items of property" are to be "charged directly to current expense" so as in part to compensate for the wasting of assets, or, to keep the assets at par? This is not an exact method, nor is any method used for covering "depreciation" mathematically accurate. Just so surely as dependence is placed on any method as being mathematically accurate, just so surely will we go wrong. We can keep nearest to the truth only by constant watchfulness and the constant exercise of common-sense methods, including full co-operation between the several departments of design, construction, operation and accounting. After which there should be full and frank co-operation between the corporation and the commission.

Page 44.—"Decisions of Courts and Commissions in Regard to Depreciation."—Commission and Court decisions, as affecting depreciation, cannot be followed blindly, because, as has been well said, "the subject of depreciation as affecting values has never been presented adequately to any rate-fixing tribunal." The writer would enlarge on this by saying that one reason why the presentations have not been adequate is because of the lack of adequate preparation and training on the

Mr. Humphreys.

part of commissioners and judges, and so they have not been able to understand the presentations as made; and, again, we may be reminded that these decisions are not in agreement with each other. Then how shall we choose?

The Minnesota Rate Case is much quoted, and will largely influence the determination of the questions under discussion until reversed or amended by later decisions. In the meantime that decision should not necessarily control our judgment. With due respect to all concerned in this case, the questions involved in "depreciation" were not adequately presented. Furthermore, this case does not sustain deduction for accrued "depreciation" due to expired life. Justice Hughes does not define what or how much should be deducted. It is quite possible that he may have agreed with the New Jersey Commission and with Judge Hough in the Consolidated Gas Case (New York) to the effect that the deduction, if any, should be confined to such an amount, generally comparatively insignificant, as would re-establish the property in a thoroughly efficient present condition from the operating standpoint. This is a very different proposition from deducting for accrued estimated "depreciation" due to aging.

As stated by H. P. Gillette, M. Am. Soc. C. E., in his discussion of the paper by W. J. Wilgus, M. Am. Soc. C. E., on "Physical Valuation of Railroads",* referring to the Minnesota case:

"The inconsistent use of words and lack of proper definitions of terms account as much as anything for this erroneous ruling, for the Court was attempting to use symbols which it did not fully understand, and did not understand because they were not clearly and properly defined by any witness."

It is not for us to follow meekly any decision which, from our special training or experience, we believe to be in error. For instance, on page 46 the report quotes an opinion by Judge Gray in which he states that while the majority opinion of the Court is in favor of "straight-line" computation of "depreciation", he is "personally of the opinion that the creation of * * * an amortization fund furnishes the best rule for adoption." And it is this last rule which has more generally been followed by Courts and commissions.

Judge Haight's concurring opinion gives his reasons for accepting the "Straight-Line" Method and for rejecting the sinking-fund plan, which reasons are by no means convincing. For instance, Judge Haight says:

"Suppose the average life of the tangible property of a railroad, outside of the land itself, to be sixty years and the cost of reconstruction to be sixty million dollars, it would follow that one million dollars would have to be used each year in reconstruction, and that amount would have to be annually used for that purpose; but under the plan

* *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 265.

Mr. Humphreys.

adopted in this case, instead of deducting from the gross earnings the amount necessarily expended for that purpose, a small fraction of that sum, viz., $4 200, only is allowed to be deducted, a sum which, with interest compounded for the next 60 years, would amount to a million dollars. Under such a plan the company would be practically prohibited from annually constructing a portion of its road and thus prevented from keeping it in that state of efficiency which the public demands."

This quotation shows conclusively that Judge Haight did not understand the Sinking-Fund Method, as applied to meeting "depreciation"; and also that he did not understand that the assumed life of a plant in connection with the "depreciation" problem means the average life of the plant, as made up from the assumed life of the many parts of plant, these parts of plant to be renewed at different times widely apart, and parts of the plant to be renewed a number of times before the end of the 60 years. The sinking fund, in fact, is thus seen to be the sum of many sinking funds, each fund being designed to provide for the renewal of its life-group. And so, the sinking fund, being made up to meet the renewal of each life-group of plant, the money will be found in the fund as required; or, rather, would so be found if the life of each part as carried into the average were found to be as assumed.

Furthermore, evidently, Judge Haight failed to see that this "depreciation" is the accruing loss over and above the current expenditures for repairs and minor renewals; in other words, the current up-keep or maintenance. Still further, there is no warrant for contrasting the expenditure of $1 000 000 a year on the straight-line plan, with $4 200 a year, on the sinking-fund plan. As Judge Haight states, the $4 200 a year would produce at compound interest (at 4%, though not so stated) only $1 000 000 at the end of 60 years; whereas, the fund would have to produce at the end of the 60 years, $60 000 000; and for this the annual sinking-fund payment required would be $252 000 instead of $4 200.

The Committee (page 40) has declared that the "Straight-Line" Method, as approved by the New York Court of Appeals, is "inequitable" and "permits the corporation to earn for depreciation in the earlier years a larger sum than is necessary to maintain the full value of its investment."

Although, as before explained, the writer differs from the Committee in believing that the "Straight-Line" Method is necessarily inequitable, if engineers can agree on one point here suggested, in addition to the other points open for agreement as set forth in the report, a great gain will have been made, namely: that commission and Court decisions and opinions are not to be accepted blindly by those who have the right to believe they are by training and experience better informed on certain of the elements involved than are the commissioners and judges. (See Judge Prouty's statement previously quoted.)

Mr. Humphreys.

Much of the confusion of thought on this vexed question of "depreciation" comes, as it seems to the writer, from the fear on the part of the corporation representatives, and the rather general opinion on the part of commissioners and judges, that if a deduction for "depreciation" is not made in valuations of property, then the right to demand an annual allowance for "depreciation" (deferred renewals) is surrendered. This error would be less in evidence if we stopped talking about "depreciation" and turned our thoughts to deferred or periodic renewals.

To render adequate service, the whole plant must be kept in continuous service, and at the same time money must be earned to renew the plant as the deferred renewal dates mature. In the meantime, it is not 90%, or 80%, or 70%, or 60%, or 5% of the plant which is rendering service; and the test to be met by the corporation, as far as the purchaser of service and the commission are concerned, is the adequacy of that service.

Unfortunately, this test is ignored by some of those who influence strongly the views of the commissioners and judges.

The following brief quotation is from a paper read before the convention of Railway Commissioners in October, 1913, entitled, "Depreciation and its Relation to Fair Value", by Dr. A. F. Webber, Chief Statistician of the New York Public Service Commission, First District, to whom the writer has previously referred:

"When that contention is made [not to deduct for estimated 'depreciation'], I always feel like asking whether a grindstone that is owned by a traveling scissors-grinder is worth 100 per cent. of its value after it has been half worn off. Of course, it may do its work just as efficiently as a new grindstone, but certainly the peddler could not obtain 100% of the value—and by that I mean the cost—after the grindstone has been half worn out."

The writer's reply to this is, that the grindstone would not bring as much as a new one if the scissors-grinder should attempt to sell it; but, if he is to stay in the business, he will continue to use the grindstone until he has to buy a new one because the present one has become inefficient; and in the meantime he must provide for the cost of the new grindstone in his charges for grinding. This he can do without change of rate due to the aging of the grindstone, for, as Dr. Webber says, "Of course, it may do its work just as efficiently as a new grindstone." Those who entrust their scissors to this man do not know and do not care how much or how little the grindstone has been reduced from its original diameter. They do care, though, as to how well the scissors have been ground. The scissors-grinder is not selling grindstones; he is selling service.

The writer will quote from this paper once more:

"In a memorandum on 'Depreciation In Its Relation To Value' recently submitted to a commission by the attorney for a lighting com-

Mr. Humphreys.

pany involved in a rate case, he declared that the opinion of the United States Supreme Court in the leading case of Knoxville *vs.* Knoxville Water Co. should not be interpreted to the effect that 'accrued depreciation must be deducted from reproduction cost new in order to ascertain the fair present value of depreciable tangibles', and then went on to say that 'The subject of depreciation as affecting values has never been presented adequately to any rate-fixing tribunal. As a consequence there have been conclusions which are absurd. To use a homely illustration, it is as if it had been determined that the price which a farmer is entitled to receive for his milk should be measured by the unexpired, normal, useful life of the cow from which it is drawn'.

"The illustration is a most unfortunate one for the argument against the deduction for depreciation in determining fair value, because age is a very material factor in the price or selling value of a cow. Nowadays, when a milch cow is kept in the dairy only four or five years, a farmer who could be induced to give up as much money for a six-year-old cow as for a two-year heifer would not continue long in business unless he had some property still unencumbered on which he could borrow funds. The mere fact that the attorneys who argue public utility rate cases are usually city men who have forgotten all they ever knew about cows and horses seems hardly sufficient to explain their attitude, because the automobile that carries them on their daily round of business and pleasure is a standing protest against their ingenious sophistries. I have yet to meet a lawyer who is willing to pay as much money for a used car as for a new car!"

The writer agrees with Dr. Webber that a "most unfortunate argument" has been presented, but is afraid that he does not agree as to the person responsible for the "unfortunate argument." As he is not the owner of an automobile, but is the owner of a considerable number of horses and cows, perhaps he is able to face Dr. Webber's bucolic sarcasm.

The attorney quoted was not talking about the price or value of cows, but about the price or value of milk. The farmer must get such a price for his milk that he will have in reserve enough to buy a new cow (or shall we say heifer) when the present cow permanently dries up or is not longer profitable or safe as a milker, and in the meantime he will go on charging the same price for his milk—that is, for his service to the milk buyer. He will not charge a graded price for the milk according to the age of the cow which produces it.

Page 47.—"A Fallacy in the Discussion of Depreciation."—The report says:

"At the risk of repeating what has already been stated, the Committee will refer again to the fallacy of the view expressed by engineers of much experience in valuation, that rates based upon the depreciated value of a property are necessarily lower than those based upon its full value."

Those who disagree with the Committee on this subject of "depreciation" might in turn claim that the Committee is advancing the

"fallacy". The Committee quotes from the writer's discussion on the paper, "Physical Valuation of Railroads," by William J. Wilgus, M. Am. Soc. C. E. (page 49), as follows: Mr. Humphreys.

"'In the case of a public utility, adequately maintained and rendering efficient service to the public, to deduct for accrued depreciation according to the practice of some of our theorists, necessarily results in confiscation of investment.

"'Certain appraisers of reputation have taken the ground that if, for instance, railroad ties have an effective life of 10 years, and one-tenth of the total number is renewed each year, there is no need for a depreciation reserve, but the value of these ties as a whole should be depreciated 50 per cent. Nothing, according to the writer's way of thinking, could be more fallacious. The property, as far as this item is concerned, is thus maintained at maximum efficiency. What more could be done? Why then should one-half of this portion of the investment be confiscated?'

"It will be observed that the writers in all these cases ignore the fact that a depreciation allowance earned from the rate-payers is a return of part of the investment, and that after that part of the investment is returned, it is neither inequitable nor confiscatory to base future returns upon the depreciated value, which is the remaining investment in the property. They also erroneously assume that the rates necessarily decrease when the depreciated value is used."

In this the writer is charging the other side with dealing in fallacy; and, as in the case of the Committee's charge, it is simply an assertion, unless the writer can support his contention.

It is true that he ignores "the fact that a depreciation allowance earned from the rate-payers is a return of a part of the investment", and his reason for doing so is because that is not the fact. It is not a return of investment, but an item of cost, quite as much as repairs and current minor renewals. The fact that this allowance covers major and deferred renewals does not make it any more a return of investment than the amount taken from rate-payers to pay currently for minor renewals as included in repair account.

Again, the writer does assume, but not erroneously, "that the rates * * * decrease when the depreciated value is used."

He does not assume that it is so "necessarily", but he does assert that this is what does happen under commission control, and has so happened in cases in which he has been directly concerned. If the valuation is made a basis for rate-fixing, and that valuation is reduced for any reason, deduction for "depreciation" or otherwise, so far as the valuation affects the rate fixed, the "depreciation" deduction, if honestly made, must operate against the owners.

After asserting that this assumption as to the effect of "depreciation" deduction is erroneous, the report goes on:

"It is true that of the return on a given item of property, the part applicable to dividends becomes less as the property grows older,

Mr. Humphreys.

but this is as it should be; a part of the capital invested in that item has been returned and has either been invested in additions or replacements, or temporarily in a depreciation fund, so that the whole of the original investment is at all times earning returns applicable to dividends."

The writer has previously suggested that this report will give those opposed to public utilities the opportunity to claim that this Special Committee of the American Society of Civil Engineers favors deducting for accrued "depreciation"; and this without regard to the Equal-Annual-Payment Method as advocated by the Committee. In relation to this matter it is particularly to be noted how effectively this last quotation from the report could be used against public utilities, especially when quoted out of its context.

The Committee states first that it is an error to suppose that "the rates necessarily decrease when the depreciated value is used", and then goes on to say that "of the return on a given item of property, the part applicable to dividends becomes less as the property grows older, but this is as it should be." Apparently, the Committee thinks that the commissions treat public utilities more gently and generously than they have the right to demand—a tendency the writer has not been fortunate enough to experience.

Again, the Committee states, "the whole of the original investment is at all times earning returns applicable to dividends."

May the writer suggest that this shows that his charge of fallacy can be maintained, and the Committee's charge of fallacy must fall?

The Committee states that with the Sinking-Fund Method "depreciation" should not be deducted. By the Sinking-Fund Method, whether the allowances are invested inside or outside of the business, the "depreciation" fund thus invested is not primarily earning dividends, but is earning the difference between the sum of annual payments and the required 100 per cent. When the writer says "depreciation" should not be deducted, he means the "depreciation" estimated by the Sinking-Fund Method.

If the owners take the risk of investing this trust fund in extensions of plant, they should be reasonably sure of earning something in excess of the required sinking-fund accumulations, for otherwise they would not be warranted in thus investing, but should establish a sinking fund outside the business, and thus relieve themselves of responsibility as guarantors.

The "investments in additions and replacements" are made from the allowances for "depreciation" (and these allowances are less than the Equal-Annual-Payment allowances), and these payments, so far as they go into "replacements", go where they are intended ultimately to go, and in the meantime such amounts as go into "additions" are

invested in accordance with the interest compounding requirement of the sinking-fund.

The writer has already shown in detail why it is that, by the Equal-Annual-Payment Method, the pretence can be made of deducting for "depreciation." He has also drawn attention to the fact that the Committee unqualifiedly condemns the deducting of "depreciation" when computed by the Sinking-Fund Method. Then, as one of "the writers in all these cases", he advocates what the Committee approves, for his advocacy was based on the Sinking-Fund Method of computation.

Page 49.—"Past Practice has Underestimated Depreciation."—The writer agrees that this has frequently been the case. It is not true as to all cases. In many cases "depreciation" has been allowed for too generously, and in most of such cases the "writing off" for "depreciation" has carried the book value of property far below its present value, thus, under present conditions, working an injustice to the owners.

Page 50.—"Appreciation."—The following is quoted from the report (page 51):

"Attention is called to a very clear discussion of this question by Commissioner Maltbie of the New York Public Service Commission for the First District, *in re* Gas and Electric Rates of the Queens Borough Gas and Electric Company."

Then Commissioner Maltbie is quoted as follows:

"Thus, land has been taken at its fair value and not at its original cost, and the annual appreciation of land has been treated as a profit. By this method, all property is treated absolutely alike, as Judge Hough suggests."

Here Mr. Maltbie has apparently cited Judge Hough as supporting his revolutionary proposition; but this is not warranted by the facts. Judge Hough's statement referred to the capital value of the assets of the Consolidated Gas Company. He took the position that, in applying cost of reproduction, depreciation and appreciation must be applied impartially, whether this course resulted, in individual cases, in an increase or a decrease from the original cost of production.

In treating income and expense, he did not add increase of real estate value.

Furthermore, as to "depreciation," he only deducted a small amount, comparatively, to put the plan in "an operating condition" as good as new—the amount deducted was only $604 000 from nearly $50 000 000 of tangible assets.

In the writer's opinion, it is most unfortunate that a Committee composed of such prominent members of the influential American Society of Civil Engineers should be willing to endorse this opinion of Commissioner Maltbie.

Mr. Humphreys.

To take an extreme case to show the principle: if appreciation of land value alone should be sufficient in amount to give a fair profit per unit of service and then be "treated as a profit", no profit from sale of service would be required, and so the rate could be fixed at cost to deliver. Thus the owners would be obliged to accept an estimated prospective profit on their land, with this prospective profit locked up in the land occupied by its plant, and thus there would be no cash profits to cover dividends. Would the commission authorize borrowing money on these hypothetical land appreciations for the payment of dividends? Or would the owners be satisfied, in the absence of dividends, to have placed before them certain journal entries covering hypothetical book profits.

It is hardly reassuring to note that, in the opinion of Commissioner Maltbie, all this depends on "only a simple mathematical calculation." Mathematical calculations are interesting, and they form the stock-in-trade of our present-day statisticians; but they do not pay dividends, nor even buy bread and butter.

Evidently, the Committee when it wrote its report was not aware that the Appellate Branch of the New York Supreme Court, in the Kings County Case reversed Commissioner Maltbie on his unique proposition to transmute appreciation in land values into income. The Court said:

"So long as the land is held and used for such purpose increase in value cannot be considered as income and available for the payment of debts, taxes, or dividends."

Page 70.—"Summary."—Having been forced to disagree with the Committee on certain points, and emphatically as to deduction of estimated "depreciation", from valuation, the writer is more than pleased to find that he is in agreement with the Committee as to many of the Sections under the head of "Summary." He is in agreement as to Sections 1, 5, 6, 8, 9, 10, 12, 13, 15, and 23.

Section 2.—The writer is able to endorse this section if there be inserted between the words, "for" and "all", in the fourth line from the end of the paragraph, the words, "the renewals of" and if there be substituted for the words, "cease to have value", in the next line below, the words, "are displaced."

Sections 3 and 4.—The writer disagrees as to depreciation, for the reasons stated.

Section 7.—The Appellate Branch of the Supreme Court, New York, recently reversed the ruling of the New York Public Service Commission in the Kings County Lighting Case, previously referred to, that the cost of paving laid subsequent to the laying of mains should not be included in valuation. This decision has in turn been reversed by the Court of Appeals, again demonstrating that Court decisions and opinions contain no attribute of infallibility.

Section 11.—"Going Value" may be in excess of cost of producing that value, though this excess may be difficult to measure. It is not necessarily true that "development expenses connected with ordinary additions to plant are a much smaller percentage than those connected with the original plant." The development of new territory, perhaps made obligatory by commercial conditions or commission's orders, may at first be a most unremunerative undertaking. Mr. Humphreys.

Section 14.—The writer disagrees as to depreciation deduction, as explained.

Section 16.—The writer entirely disagrees as to Equal-Annual-Payment Method, and again asserts that, under reasonable conditions, there is no warrant for the statement that these combined amounts "are substantially equal in each year of the life of such item." He also holds that there is no more reason for deducting "depreciation" by this method than by the Sinking-Fund Method, except in the manipulation of figures, which transfers the decreasing return on the investment to the increasing charge for depreciation.

Section 17.—As already explained, the writer does not agree with the Committee's statements or conclusions as to the Sinking-Fund Method.

Section 18.—There is no reason why the "Actual Inspection Method" cannot be made to operate fairly to corporation and rate-payer. In fact, inspection is necessary, and no proper valuation can be made without inspection.

Section 19.—To treat appreciation in the value of occupied land as income, instead of as increase of asset, is unworkable, indefensible, and absurd.

Section 20.—There is no objection to paying proper regard to the Minnesota Rate Case, but that decision is not necessarily to be followed for general application, and is a good subject for amendment in certain particulars.

Section 21.—Deficiency in past earnings may properly be taken into account in determining whether the replacement of plant rendered obsolete by sudden and unexpected changes in the art has been provided for in the income from rate-payers.

Section 22.—If the value can be found in the property, whether produced by cash expenditures or by fortunate circumstances united with foresight, the property as a whole belongs to the corporation.

Although the writer has taken much space to express his views on the questions treated, it is not necessary to state that the opportunities for misunderstanding are so many, and the questions are so momentous, that all may feel justified in making every possible effort, including repetition and paraphrasing, to reduce the chance of misunderstanding to a minimum.

J. H. H. Muirhead, M. Am. Soc. C. E.—Noting some confusion as to the meaning of certain terms, the speaker suggests that the Com- Mr. Muirhead.

Mr. Muirhead.

mittee include in the report some decided and definite meanings of the technical terms. One word has been used by one member to mean a certain thing and by another to mean something entirely different. At the same time some members have offered explanations of a modern nature for some terms, and therefore far in advance of the various dictionaries. Something of this nature should accompany the final report.

Public utilities come under three headings. First.—Utilities such as railroads, telegraphs, telephones, etc., of an interstate nature owned and operated by corporations the stocks and bonds of which are owned by the general public. Second.—Public utilities owned and operated by municipalities. Third.—Public utilities (like the New York subway) owned by a municipality but in the hands of an operating company.

It would be advisable that municipal corporations coming under the second and third classes be not considered in the report, as they differ radically and essentially from the utilities under discussion. Cost data referring to one class could not fairly be applied to the other.

It has been considered one of the strong points of the Society that each member speaks from his experience, but in this case the speaker regrets that though an intimate knowledge of water-works has been shown, comparatively few of those having a practical knowledge of railroad construction and the detail of maintenance have discussed the subject.

The report abounds in extracts from Court decisions; some of these are good law, others very bad engineering. Where Court decisions are bad engineering, in the opinion of the Committee, it is its duty to set forth the fact clearly in the report. It is safe to assume that the Courts would be greatly influenced by the conclusions arrived at by this Society. The speaker goes further, and does not hesitate to state that this report will influence, not only the United States but the whole engineering and legal world, in so far as engineering applies to law. Therefore, as a Society, we cannot be too careful in what we say in the final report.

These words occur on page 6: "a fair return and no more." What is a fair return? Without discussion, reason, or stated authority, many have selected 8% as a fair return for an investment. It is surprising that this has gone so far without challenge. There is some reference to what are called "losing ventures," which is an admission that, although 8% may be aimed at, a minus quantity may result. Had 8% been the expected profit, the great railroads of the United States would never have been built. Some have stated that losing ventures do not count. The country must have railroad service. The very life of its industries demanded the existing railroads, and the

Mr. Muirhead.

increase of population will demand their extension, whether they are losing ventures or not. Railroads going east and west are said to pay better than those going north and south. Be this as it may, the weak must be carried by the strong. The rates must allow an excess on paying railroads to enable them to form a complete system containing those so-called "losing ventures". The report admits unknowns and probabilities which bring out the fact that "anticipated profits take unto themselves wings". The original risk in building the great railroads was enormous. A few years ago it was assumed by all that the railroads were on a fairly steady financial basis, but things spring up, as it were, in a night, and to-day we do not know where we stand.

The recent action of the Federal authorities in placing the Panama Canal free to the commerce of the coasts was almost a confiscatory action, so far as the railroads are concerned for the next few years. It shows very clearly that the roads had some confidence that this act would be repealed or we would have a worse panic than exists to-day. The fear of adverse or confiscatory legislation must be reckoned with; in truth, it is worse than the prospects of fire, storm, pestilence, or even war. Strikes are becoming a certainty, instead of a possibility. Considering all these risks, the speaker claims that 8% is quite inadequate as a maximum profit to aim at in making our costs for the construction, maintenance, and depreciation of a public utility.

A great many are so accustomed to New York State that their vision does not go beyond it. In such a steady place, 8% is a good investment; but there are first mortgages on agricultural land in a high state of cultivation that can be had in other States at 10 per cent. This being so, can it be expected that the public will be contented or continue to invest in railroads at a possible maximum of 8%, subject to all the risks attendant to-day on unsettled political conditions?

In considering stock, there has been no mention, so far, in the discussion or in the report itself, of the double condition "stocks and bonds". There are a great many utilities in which it is the custom to pay a fixed rate of interest on bonds, or for money actually borrowed by the company, perhaps for an improvement or extension, while at the same time profit has to be made on the utility for the benefit of the owning company on its stock. It is this stock that is so often referred to as "water," a term that agitators have used against the public interests. Sometimes this stock is given for services; at other times it is sold far below its face value. It is often held for years without profit while bonds are being paid off; surely it is worth consideration. The speaker is much impressed by a modern theory that the dollar mark has no place on stock certificates, and is only misleading. He inclines to the theory that the stock certificate should show what fraction of the entire property it represents after bonds, etc.,

Mr. Muirhead.

are paid. He firmly believes that, had this system been inaugurated some few years ago, the present valuation would never have been started. It is not out of place to remark that the meaning of the terms, stocks and bonds, is far from being understood by the general public, or even by those individuals fortunate enough to be owners of both.

Possibly the most valuable thing some utilities own is their franchise. The speaker has heard no reference to the value of the franchise. There is some reference to the "physical value" of a utility, but there is not sufficient stress on the fact that the physical is not the actual value. The franchise is often obtained at an enormous cost. Page 22 states: "all necessary permits from public authorities are obtained". To this might be added the words: "often at an enormous cost". It is not just to neglect this in after years. The speaker cannot agree with the remarks on page 20, under the head of unit prices, but inclines to the belief that the unit prices used should be as nearly as possible those expected to prevail during the life of the rates which are adopted as a result of the valuation. Certainly, no price lower than that of material at the date of valuation should be used. Some material, due to the removal of the tariff or to improved methods of manufacture, may be counted on to fall in price, but that is the exception rather than the rule. The prices of some materials fluctuate; then an average would be fair; but the inclination is for prices to keep on increasing. This is particularly true in the case of timber, for the increased cost has been so great that, in spite of an easing up of specification and inspection, its use for many purposes has been discontinued.

On page 22 are the words: "and for many other things". What are these many other things? The things never thought of and never mentioned. One of these things is lobbying. It is necessary to lobby to start a railroad or other public utility, and it is necessary to lobby to keep that utility in life. True, some of these "many other things" are illegal and punishable by fine and imprisonment; at best it is dirty work and must be done, or public utilities would come to an untimely end. Lobbying, being one of the expenses of starting and maintaining a public utility, must in the end be paid for by the public, and it could be placed before the public in no better way than by having it honestly, forcibly, and fearlessly set forth in the limelight by this Society. The standing and the well-known honesty of the Profession make the speaker feel confident that to all it is a matter of disgust, but whether it is or is not, it is there, and in the meantime must be acknowledged under some name or other, and, unless openly acknowledged, the condition will never be improved. Disgusting as this condition is, it must be admitted that worse conditions have been

tackled by engineering bodies and abated with wonderful success. As a rule, engineers are not well versed in these matters, and therefore make insufficient allowances. Mr. Muirhead.

The second paragraph on page 67 is the most surprising part of the report. There are cases where railroad banks have been top-soiled and sodded by contractors engaged for this special purpose. Other banks have been carefully cut and cultured for many years. If, in the Committee's opinion, this has no place in the valuation of the property, the speaker respectfully declares a decided difference of opinion.

Under the head of depreciation the report is academic rather than practical. The methods of depreciation given apply more to the first few years of the existence of a new utility than to the valuation of an old one. For instance, should legislation favorable to the development and application of water-power for traction purposes become law, it would immediately retire locomotives in such numbers that they could not be disposed of. Then again, did not the steam turbine put all its competitors out of business in the generation of electricity? Is not the Diesel engine busy throwing out the steam turbine? What next?

The condition of railroad ties, rails, telegraph poles, etc., should be a matter of exact knowledge, in decided preference to an academic formula.

For many years we have had railroad rates which experience has shown have allowed a fair return on the investment. Recent legislative interference has very much reduced this return, and it is only fair that the rates should be raised. It may be remarked that the whole subject has been illustrated by the Italian railways as reported by the *New York Times*, as follows:

"The session of the Chamber of Deputies of Italy on Sunday gave a good example of the short and easy way to deal with railway wages and rates. Something like 100,000 railway men are threatening a general strike, and the Premier surrenders at discretion. He enlarges the pensions of the employes of the State railways by 11 per cent. He raises the minimum wage, and incurs obligations enlarged by $3,000,000 annually. In the words of the cablegram, 'This sum would be obtained by increasing the railway rates'. It's no harder than that, where Governments own the railways. The Deputies clinched it by a vote of 303 to 122. The reason why it is so easy is that 'the unions of railway men transform themselves at election time into instruments for collecting votes.' Those who like increases of railway rates, and politics dominated by unions, must like the example Italy affords of Government owned and operated railways."

CHARLES KIRBY FOX, Assoc. M. AM. SOC. C. E. (by letter).—The writer has read this valuable report and the discussion on it with a great deal of interest. Though, in general, he is in sympathy with most of the conclusions set forth, especially the so-called Equal-Annual- Mr. Fox.

Mr. Fox.

Payment Method, he is of the opinion that some of these conclusions are deduced from the valuation of minor and somewhat localized utilities. According to his understanding, the Committee was appointed for the specified purpose of formulating principles and methods for the valuation of railroad property and other public utilities. The art or science of valuation, in spite of the abundant literature on some phases of the subject, is comparatively new, and rapidly changing and improving. For these reasons this report should be received by the Society without any endorsement other than to thank the distinguished authors for their careful and painstaking work.

The valuation of utilities for the various purposes is probably the greatest single economic question before the American people to-day, affecting as it does practically untold millions of wealth, the income, wages, and prosperity of a large percentage of our people and to a certain extent the living expenses of practically every inhabitant. Probably the prosperity of no single class is affected as much as that of the civil engineer.

Although this report distinctly refers to valuation for rate-making purposes, the methods and principles involved are practically the same as in the valuation for other purposes.

In the last few years a great many so-called "muck-raking" articles have been published tending to create and mould public opinion to believe that nearly all public utilities are over-capitalized and the stock badly watered. Among well-informed people it is almost universally conceded that American utilities, as a whole, are the lowest capitalized, best managed, most efficient, and cheapest in the world.

It is almost always conceded that valuation is only one of the factors involved in rate-making, and that the rate should earn a fair amount on the capital invested. These two statements do not go together, and the second should be modified in order to take in the element of risk, so that, where a venture is in a new and untried or risky field, and there is a possibility of failure, the rate should be increased to cover this item and give the capitalist a chance to recuperate for other losing ventures in similar fields. That is the most important criticism the writer can offer in regard to this report and practically all other valuation literature.

Mr. Thomson.

T. KENNARD THOMSON, M. AM. SOC. C. E.—The Society is very much indebted to Mr. Stearns and his Committee, for the courage and industry with which they have attacked this stupendous problem.

It seems almost as difficult to try to lay down, in advance, a schedule for a new or even an old corporation, governing the amount that it should set aside each year for depreciation or renewals, so that, at the end of a fixed term of, say, 10, 30, or 50 years, the fund would be sufficient to renew the plant, as it would be to estimate what a young man, just out of college and about to be married, would be worth at

Mr. Thomson.

the end of, say, 40 years, and to order him to set aside a fixed proportion of that amount each year, so that when he was too old to work, or dead, his wife would have enough money in the depreciation account to purchase a new plant or renovate the old one.

The report of the Committee and the various discussions thereon naturally cover a great many phases of the subject, and many pages, to read all of which, by one anxious to obtain information for some particular purpose, would be a very arduous undertaking. It is to be hoped, therefore, that, when the discussion is all in, the entire report will be entirely rewritten, divided into proper headings, and indexed so thoroughly that any engineer, lawyer, or layman can readily obtain the opinions of the Committee or individuals on any branch of the subject.

Mr. Sparrow.

W. W. K. SPARROW, ASSOC. M. AM. SOC. C. E. (by letter).—In a previous discussion* of this report, the writer dealt with the questions of "Going Value" and "Land Values", and now, after further study, proposes to take up the question of "Depreciation and Appreciation."

Probably more has been written on depreciation than on any other question connected with the valuation of public utilities, and the greater part of the discussion on the report of the Committee has centered around this subject. The writer will first deal with the method of computing the amount of the annual depreciation, and then take up the question of whether rates should be based on the depreciated value or the value new.

The Committee has offered for consideration five different methods, and of the five, the writer is in favor of the Straight-Line Method, Value of Plant, Depreciated, because of its greater simplicity both in accounting and in being understood. It is true, as pointed out by the Committee, that the Straight-Line Method calls for a higher annual return in the early years of the property, which is just the time when it can be least afforded, but it is believed that, if regulation of public utilities has come to stay in the United States, public service commissions and other regulating bodies must see that rates are fixed so that *bona fide* new enterprises will be enabled to earn sufficient to set aside a proper and adequate depreciation fund, for otherwise such rates are not fair or reasonable. This being so, the writer believes that this objection to the Straight-Line Method will be eliminated.

The Committee makes the claim in favor of the Equal-Annual-Payment Method that the Straight-Line Method, Value of Plant, Depreciated, requires the rate of return to decrease annually. Theoretically, this is correct in dealing with an imaginary plant which in a definite period depreciates from 100% to 0, but, in actual practice, a successfully operated plant has a perpetual life, and the annual allow-

* *Proceedings*, Am. Soc. C. E., for February, 1914, p. 361.

Mr. Sparrow.

ance for depreciation will be used either in replacements, or in additions and betterments, until such time as it is required for replacements. Looking at the matter from this standpoint, it does not appear that of necessity the rates must be changed in order to do justice to the public. For the purpose of illustration, assume that a utility had started with a $100 000 property, and that under regulation the annual return for depreciation had been fixed at 5% per annum. At the end of 10 years, the company would have had paid to it, on account of depreciation, $50 000. Assume that this property had been kept up to a high standard of efficiency and that $30 000 had been expended in replacements, leaving the condition percentage of the property 80. Assume, further, that the remainder of the earnings on account of depreciation, or $20 000, had been re-invested in additions to the property. On the basis of the present value of the property in use and useful service, the company would be entitled to a return on a capital value of $100 000, whereas, if the rates had not been changed on account of the original investment having depreciated 20%, it would be receiving a return on $120 000. This assumption, however, presumes that the investment in additions would yield the same net revenue percentage as the older and fully developed property. This is very improbable. In the case of a street railway, electric light plant, telephone, or water plant, extensions will generally be made to new suburban districts or outlying property which is not built up or thickly populated, and such extensions, on the rates already fixed, will be hardly likely to earn much if any profit.

This illustration presupposes that the earnings on account of depreciation have been used in replacing depreciated property and in additions, and the writer anticipates that under regulation the depreciation fund will be safeguarded so as to insure that it will be used in such a manner and not invested outside the property for the direct gain of the company.

At a recent meeting, before the Public Service Commission of the State of Missouri, of representatives of the various public utilities operating in that State, to consider the adoption of a uniform system of accounts, the great desirability of allowing the utilities to borrow from the depreciation fund, at a reasonable rate of interest, such sums as they might require from year to year for additions, was very strongly impressed on the Commission. It was pointed out that this would save the companies from having to borrow small sums in the open market at a high rate of interest and, consequently, would decrease the cost of the service. Under a strict accounting, there could be no objection to such use of the company's earnings on account of depreciation until such time as required to replace depreciated property of long life, and this appeared to be the view of Mr. McShane, Chief Accountant for the Commission. If the utilities were allowed

Mr. Sparrow.

this advantage of obtaining money for additions at a low rate of interest, the public would benefit indirectly, inasmuch as such additions and extensions would be more easily obtained and the cost of the service would be less. Under effective regulation, it is reasonable to suppose that rates will be subject to review at intervals of about 5 years, and, if a uniform system of accounts is in force, it will be very easy for the regulating body to ascertain whether a utility is making more than a fair and reasonable return on the present value of the property, whether due to an excessive return on account of depreciation or for any other cause, and, if so, to adjust matters.

The Equal-Annual-Payment Method, as recommended by the Committee, has the advantage over the Straight-Line Method that it does not require any change in rates, and only allows a return to the utility on the present value of the property. The writer has two objections to this method: first, that, as already stated, it is difficult to explain to non-technical men, which is a great disadvantage, and it requires a more complicated method of accounting; and, second, that the annual payments are not equal unless the interest on depreciation is the same as the rate of return fixed on capital.

Should Rates be Based on the Present or Depreciated Value?—The writer fully endorses the recommendation of the Committee that rates be based on the depreciated value of the property, the Sinking-Fund Method excepted. There has been a great deal of discussion on this question, and the weight of it has been against the recommendation of the Committee, but the writer has not been convinced by any argument in favor of the public continuing to pay a return on a portion of an investment which it has paid back to the company.

On page 32 of the report, the Committee states:

"A depreciation allowance is, in effect, a payment from the rate-payer to the corporation of a part of its investment, and such part of the investment as has thus been repaid should not appear in subsequent valuations of the property."

This is a very clear, concise, and fair statement, but one for which Mr. Floy, in a recent discussion,* takes the Committee to task.

Mr. Floy says:

"The Committee * * * has developed a unique theory of estimating and providing for depreciation, the allowance therefor being stated to be, 'in effect, a payment from the rate payer to the corporation of a part of its investment'. This is certainly a novel definition, and one that is contrary to accepted practice."

If a company invests $100 000 in a public utility, and if, at the end of 4 years, it has collected from the rate-payer, in addition to its operating expenses and a fair return on its investment, $20 000 for the specific purpose of returning to the company the value of the

Proceedings, Am. Soc. C. E., April, 1914, p. 1129.

Mr. Sparrow.

property which has been worn out or partly worn out in its service, what does this constitute? If it does not constitute a return of a part of the company's investment, the writer is forced to admit that his views on accounting are very foggy. To the writer, the novelty is all in Mr. Floy's statement, and if he is correct that in the East such a transaction is not considered a partial return of the investment, then the rate-payer in the East has a good deal to learn from his brother in the West. The United States Commissioner of Internal Revenue, under date of December 15th, 1911, issued a synopsis of decisions relating to the special excise tax on corporations. This synopsis contains the following rule:*

"83. Depreciation to be an allowable deduction in the return of annual net income of a corporation must be charged off on the ledger of the corporation, so as to show a reduction in the capital assets of the corporation to the extent of the depreciation claimed."

If money paid on account of depreciation does not constitute a return of the investment, why does the Commissioner of Internal Revenue specify that capital account must be charged off to the extent of the depreciation claimed?

If Mr. Floy would obtain for publication by the Society the opinion of a competent and disinterested accountant in support of his statement that "money paid by the rate-payer to the corporation on account of depreciation is not in effect a return to the corporation by the rate-payer of a part of its investment", the writer believes that he would perform a service which would be appreciated by many members of the Society.

Mr. Floy labors hard to show that the decisions of the Supreme Court of the United States do not lay down the principle that depreciation must be deducted from the reproduction-value-new in order to arrive at the present value of the property. He construes the decisions in the Minnesota Rate Case to mean that only actual depreciation should be deducted, and not theoretical depreciation. The writer cannot agree with this interpretation of the opinion, but, even if Mr. Floy were correct in his views, it does not seem to the writer to be very material. The real and vital question in any particular case is, what method has been used in computing the annual return for depreciation? If theoretical depreciation, as Mr. Floy terms it, has been included, then theoretical depreciation must be deducted in arriving at the present value. The Committee has very clearly shown that the amount on which a company is entitled to a fair return is inseparable from the method used in computing the annual return for depreciation. This is also emphasized by Mr. Maltbie in his discussion.† If this fundamental principle were clearly understood,

* Taken from Whitten's "Valuation of Public Service Corporations," p. 409.

† *Proceedings*, Am. Soc. C. E., for April, 1914, p. 1126.

a long distance would have been traveled on the road toward a satisfactory solution of this subject. Mr. Sparrow.

Mr. Willoughby, who confines his discussion* to railroad property, is also unable to accept the statement of the Committee that "a depreciation allowance is, in effect, a payment from the rate-payer to the corporation of a part of its investment." His reasons appear to be based on the fact that the present method of railway accounting charges replacements to maintenance which is an operating expense. Admitting that railways are in a different class from other public utilities, that depreciation on rails, fastenings, cross-ties, ballast, wooden bridges, and trestles, accumulates quickly, and that the annual operating expenses care both for the depreciation and maintenance, does this affect the underlying principle involved in the statement of the Committee? The earnings on depreciation of such short-lived property, where such earnings are put back into the property from year to year, are not involved, and it is purely arbitrary whether such expenditures are charged against depreciation or maintenance. It is plainly impracticable every time a section foreman renews a cross-tie to carry this through the books as a charge against depreciation, just as it would be impracticable in the case of a telephone company to make a similar charge every time a lineman replaced a broken insulator. For convenience such small charges are regarded as maintenance. In the case of property of long life, however, such as, say, the Quebec Bridge or the Pennsylvania Terminal Station, where the company earns each year from the public a depreciation allowance, would it be fair for the company, while the depreciation is maturing for a period of perhaps 50 years, to earn interest on such earnings and, at the same time, collect from the public a return on the full value undepreciated? Apparently, Mr. Willoughby does not think so, as he says that:

"The only injustice which the public can assert is that the rates paid during the period in which the depreciation was maturing have been converted to the use of the owner without an allowance for interest, and possibly have been used for dividends to the owner. It is the opinion of the writer that justice to the public requires an interest allowance during the period the depreciation is maturing * * *"

The writer agrees with Mr. Willoughby that if this were done the public would suffer no injustice, provided the rate of interest on such depreciation were the same as on capital. To the writer, however, the same principle is involved in Mr. Willoughby's statement, unless he misunderstands him, as in the statement of the Committee, for the only reason for the company to set up in its accounting such a liability recognizes the fact that it is only holding in trust such earnings

* *Proceedings*, Am. Soc. C. E., for April, 1914, p. 1117.

Mr. Sparrow.

from the public during the period the depreciation is maturing, and that, when matured, these earnings will be used to restore the original investment.

Mr. Willoughby will no doubt agree that the normal condition percentage of the physical property, excluding land, of a well-managed railroad which has been in operation for some 20 years, is about 80%, and that it would be impracticable, of not impossible, to maintain it at 100 per cent. This being so, what has become of the remaining 20 per cent? Either the railroad company has collected it from the public over and above its operating expenses and a fair return, and has paid it back to the stockholders in dividends or reinvested it in other property, or it has not. In the former case, it has most certainly had 20% of its original investment returned to it, and it is clearly not entitled to earn a return on it still, and, in the latter case, it would certainly be an injustice and confiscation of property to deny the company a return on it. The fair thing to do would be to allow the company to amortize the amount in a given period.

A number of writers who argue in favor of the rate of return being based on the value of the plant undepreciated, build up their case on the foundation that the service the public is receiving from the corporation is just as good or, in fact, better in the case of an old and seasoned plant. Although this argument is plausible, it is fallacious and inconsistent, for the reason that service is not the basis on which we started to determine the fair rate of return. The Courts have ruled, and it is, at present, an accepted fact, that the fair rate of return shall be based on the present value of the property in the use and useful service of the public. This being so, and having started on this theory, surely it is inconsistent and improper to switch to another theory based on the "value of service." If value or worth of the service is to be the criterion on which a return is to be fixed, why go to all the expense and trouble of making a physical valuation of the property? If a street-car company, in, say, Milwaukee, is charging 5-cent fares with universal transfers, and this has been established as a fair and reasonable charge for this class of service, it would be entirely unnecessary, in, say, the case of Kansas City, to make a physical valuation. If service is the basis, then the only question is, is the service in Kansas City up to the required standard? and it would be immaterial whether in the case of Milwaukee this charge yielded a net return of 7% and in Kansas City 12 per cent. Such a method of fixing rates would be very unfair to the rate-payer, and would involve a very dangerous principle which would open up an avenue to fraud and imposition at the expense of the public. To illustrate this, suppose a corporation invested $10 000 000 in a utility and at the end of, say, 5 years, had collected from the rate-payer, on account of depreciation, $2 500 000 (being at the rate of 5% per annum) and of

this sum had only expended in replacing the depreciated property $500 000, then the depreciated value of the property would be 80% or $8 000 000. At this stage the original company decides to sell the property and, on the perfectly legitimate basis (assuming that the rates are based on service and not on present value) that the investment is yielding a fair return on $10 000 000, sells it for this amount. The net result is that the original company retires with its original investment of $10 000 000 and $2 000 000 to boot, which has been collected at the expense of the rate-payer to replace depreciated property. Mr. Sparrow.

No doubt this will be considered by many to be a far-fetched supposition, but in view of some recent manipulations, disclosed by investigations of the Interstate Commerce Commission, where railroad manipulators bought properties which they unloaded on their unsuspecting stockholders at huge profits, it is not perhaps so improbable. At all events, it would tend to show the unfairness and absurdity of fixing the rate of return on anything but the present depreciated value.

Adaptation and Solidification of Roadbed.—On this question the Committee, in its report (page 66), makes the following statement:

"A railroad roadbed, built of earth that has been dumped without consolidation will, as the result of running trains and the effect of weather conditions, settle, and earth will be washed from the fresh slopes, so that additional earth, ballast, and labor will be required to produce a solid and full-sized embankment. All such costs required to complete machines and structures are properly chargeable to capital account, and if the unit prices used in making the valuation do not cover these items, they should be added."

The writer cannot accept this statement, which is, pure and simple, a recommendation that operating expenses be capitalized. It might possibly be argued that in the early life of the property the earnings did not yield a sufficient return to pay such operating expenses and at the same time pay a fair return. This, however, is cared for in the Committee's recommendation that such losses shall be capitalized as development expenses. If the company has earned a fair return and paid for such adaptation and solidification of the roadbed out of operating expenses, it has no right to expect to capitalize such expenses. If it has not been able to earn a fair return and pay these operating expenses, it will, under the Committee's recommendation, be allowed to capitalize them under development expenses; and, of course, it would be improper to capitalize them twice.

J. P. Snow, M. Am. Soc. C. E. (by letter).—In the discussion of depreciation methods published in the *Proceedings* of May, 1914, the writer says, at the bottom of page 1390: "The final outcome at the end of the life cycle is the same if interest is fully allowed for in both cases." That is, the straight-line and equal-annual-payment Mr. Snow.

Mr. Snow.

Mr. Snow.

methods. To show that the result is identical for the four methods: straight-line, sinking-fund, equal-annual-payment, and replacement, when full interest is allowed, Table 33 is given, indicating the life history of a single 10-year item, the value of which, new, less scrap value, is represented by 100. In all calculations 7% is used. Mr. Snow.

The depreciation allowances in methods Nos. 1 and 3 are in the nature of partial payments on a note, totaling 100 at the end of the term; and hence annual return on capital must be cast on the remaining value, as is customary with the ordinary promissory note. In method No. 2 the allowances do not sum up to 100, but must be allowed to accumulate at compound interest when, at the end of the term, they will amount to 100. This is comparable to the common method of paying bonds by a sinking fund, and, of course, the annual capital return must be paid on full value new.

In method No. 4 no replacement fund is provided, but the money for replacement is raised when and as needed.

These four methods are just and equitable to all parties concerned, if properly applied, and the amount paid by the public on account of capital as combined return is exactly the same by each method, if the computations are correctly made and full interest is allowed.

The amount given in the columns of combined returns are due at the end of the year at which they are given or at the beginning of the following year. If these amounts are figured at compound interest, at the rate assumed, to the end of the term, that is 10 years for the first term and so on, it will be found that each of the four columns amounts to 196.68 if sufficient decimals are used.

This demonstration is plain arithmetic. It is a theoretical case, to be sure, but it typifies any one item of a plant, and a whole is but the sum of its parts. There is surely no more confiscation of property by one method than by another, as has been harshly claimed by some critics of the Committee.

As Whitten says: "Depreciation is a question of cost accounting." Each method requires its own system of bookkeeping, and such features as equality of rates from year to year, the feasibility of using depreciation funds regularly for replacements, and the protection of the depreciation funds from distribution as dividends, would seem to be the governing factors in choosing the method to be used.

E. W. James, Assoc. M. Am. Soc. C. E. (by letter).—A perusal of the discussion invited by the Report of the Committee emphasizes the point raised in the writer's previous comment.* There has been neglect of some fundamental matters that should be disposed of before details of methods, accounting and other forms, and treatment of peculiar or special problems are finally settled. Mr. James.

It is too much to say now that the discussion is chaotic, although

* *Proceedings*, Am. Soc. C. E., for February, 1914, p. 351.

Mr. James.

it has long had that quality in the engineering press, for the work of the Committee certainly has ample merit of form and inclusiveness to fix the lines of discussion much more definitely than they have ever yet been fixed. The discussion, however, serves to indicate that some matters of importance have been passed by, and until these matters are duly considered and the Committee issues some decision regarding them, there will remain work to do in establishing the report on the high basis of principle that should result in its general acceptance as the dicta of the Society.

For instance, a point has been raised regarding the very creation of the Committee. Now, the appointment of the Committee was under the following title: "A Special Committee to Formulate Principles and Methods for the Valuation of Railroad Property and Other Public Utilities."* The subjective form of this title does not include any reference to rate-making, but the circumstances attending the work of the Committee, and the fact that the valuation of public utilities, more particularly of railroads, has become important because of the avowed purpose of using it in rate-making, certainly makes rate-making cognate to the work of the Committee. This does not appear to be the opinion held by all, however, for both Mr. Phillips and Mr. McCarty would circumscribe the work of the Committee closely. Mr. Phillips questions the advisability and the precedents of using valuations for determining or adjusting rates, and Mr. McCarty would confine the study to the strictly technical details of a physical appraisal, and omit all consideration of the legal, economic, or sociologic details of the problem. The writer would not presume to decide, as between the Committee and these gentlemen, but the circumstance indicates that the very purpose, the *raison d'être*, of the Committee's action is still at this stage a matter about which there are differing opinions. Again, Mr. Lavis suggests that it was unfortunate that any reference was made to railroads in the title of the Committee. It would seem that 19 months is a sufficient time to establish such matters as these, if not to the satisfaction, at least to the understanding, of all.

The writer has already called attention to the existence of important underlying principles connected with the problems of valuation for rate-making, or for any other purpose, and Mr. Dana and others recognize this same fact, but although the Committee has made a substantial addition to the general consideration of the subject, it has not taken advantage of an excellent opportunity to formulate these principles or to define terms.

The original report, however, is doubtless only a consideration in part of the general subject assigned to the Committee for investigation, and, if so, there will still remain an excellent opportunity to consider

* *Proceedings*, Am. Soc. C. E., October, 1911, p. 479.

Mr. James.

other aspects of the general question. It is to be hoped that the Committee will be continued until it has completed such studies as will serve to elucidate the fundamental principles of valuation as applicable to rate-making, to taxing, and to acquiring by purchase. The general title of the Committee permits this to be done. There is no doubt that such a task—for task it certainly would be—will be attended by valuable results.

Without going to any great length in supporting the question, the writer wishes to point out certain actual conditions obtaining to-day in the valuation discussion.

There is a lack of definition. Although this phase of some branches of engineering has been rather overdone recently, no mistake can be made in stating clearly what is meant by cost-of-reproduction-new, original-cost-to-date, depreciation, deterioration, depreciation-reserves, and the commoner terms used in connection with valuation matters.

For instance, the exact meaning of cost-new (or cost-of-reproduction-new) should be considered and stated. The Committee might state it thus: The term "cost-new" is to be used instead of "cost-of-reproduction-new," and it will be considered as the cost to reproduce the plant in all its physical elements or their respective equivalents as of the date of valuation, assuming that the plant is non-existent on its present site, and that the construction was begun at a sufficiently early date to reach completion at the date of valuation; and all unit prices of labor and materials, and all attending conditions, shall be assumed as of that period only.

Though the Committee would probably not adopt such a wording as the writer's, it could define such a valuation in its own terms, and thenceforth valuations on the basis of cost-new, if made as prescribed by the Society, would mean only one thing. At present, a cost-new valuation may or may not include intangible values; unit prices may be assumed on several varying bases; practically a substitute plant on a different site, bearing little or no resemblance to the existing plant, either in design or in its physical elements, may be evaluated, which, however, would produce an equivalent service; piecemeal, or continuous, construction may be assumed, in an attempt to approximate conditions under which the existing plant was actually constructed, thus confusing original cost and cost-new. If the Society, through its Committee, defined cost-new, the method could then be referred to and used as succinctly as are specifications now prescribed by the Society.

Depreciation and deterioration should be carefully defined and distinguished. Depreciation should be defined with reference to the time element involved, as an accounting term merely. Depreciation begins at once and progresses according to time elapsed, the rate for any period being approximately determinable. Deterioration, however,

Mr. James.

has reference to efficiency of service, and has no necessary connection with depreciation. As in the case of an automobile, the efficiency of the machine may be considerably higher at the end of from 1 to 6 weeks than when brand-new, and consequently the deterioration for that period is nil. Deterioration may then practically halt for several months, or even years. Deterioration has no determinable time element. It affects depreciation as an accounting element only by accident; then the unexpected happens and rapid deterioration occurs, practically compelling the replacement of a part before the estimated time for complete depreciation has elapsed.

Similarly, original cost, depreciation reserves, and other details of valuations should be defined. These definitions cannot be made satisfactory to all, but, if it is borne in mind that adjudication by the Courts will in nearly all cases be had before the fair value for rate-making purposes is fixed, and if the engineer remembers that his figures are not necessarily to include adjustments to establish equity and fairness as between the public and the owners, then the value of determining definitions for the fundamental exhibits submitted to the Courts for judicial review, will be more apparent. The engineer can appear before the Court or commission in support of various adjustments; that, for instance, certain elements of the cost-new valuation are peculiar in a given case and do not represent a fair value from the point of view of the owners; that, in certain cases, the Court should give greater weight to cost-new than to original cost; and, that certain intangible values should be specially considered. Original cost should include actual cost of land, should not include bonds guaranteed by counties or States, nor lands granted by the Government; cost-new, of course, would show land at present-day prices, with accumulated increment; values representing the gifts of land or funds would also show. The Courts would presumably determine on a fair value, using such elements of each valuation, together with other considerations, as might seem just and reasonable.

The writer has elsewhere stated at some length his ideas as to the economic and ethical considerations involved, which Courts should recognize in establishing fair values for rate-making purposes. In regard to all these details, the engineer should be informed; but it is hardly within his province to act in a judicial capacity in making physical valuations. His part is to state, item by item, the physical elements of a property, and assign to each a value. These should be classified and grouped in such a way as to show separately those items that are commonly involved in Court decisions; so that, for instance, physical value, intangible values, unearned increment, contributed land, guaranteed bonds, etc., can be quickly separated. The further part of the engineer will be to understand the relative importance of these items as they might affect a fair valuation for

rate-making in the case in question, and be prepared to defend the inclusion or exclusion of certain of them. Mr. James.

The most successful work of the Committee, it seems to the writer, will be to provide a set of principles to guide the engineer in making valuations according to the various methods, now more or less confused and conflicting.

That no established rules are being followed by the engineers is quite obvious to any one studying the subject. The commonest source of differences lies in the effort of the engineer to do justice in the premises. He cannot do it. It is doubtful if the Courts can. Under the circumstances, a rational course presents itself only when the engineer is sought to fix the value of the several items entering into a property and to give the commission or Court of final adjudication the benefit of his expert knowledge. In the end the Court will determine the fair value for rate-making purposes, taking into consideration, no doubt, numerous economic, legal, sociologic, and other special elements. The exact relation of each of these elements toward one another and toward the general whole will doubtless in time be determined by a series of Court decisions. The engineer is concerned in securing equitable decisions, on grounds as fair as possible to owner and user, in no professional way, and only as all good citizens are concerned. If called on to act as referee, as commissioner, or as final adjudicator, in any case, then he acts in an extra-professional capacity as a judicial officer. The wisdom required for his decisions in such cases will far transcend that demanded by the daily practice of his profession, and a knowledge of many things quite apart from engineering principles will be required.

George L. Dillman, M. Am. Soc. C. E. (by letter).—The "value" of a public utility, like the value of everything else, is largely a matter of opinion, and will be as various as the valuators. Neither is it constant with each valuator for any length of time. Next month, or last month, his opinion will be, or was, different from his opinion to-day. Mr. Dillman.

A valuator whose opinion is constant is necessarily wrong most of the time. The attempt to be consistent makes us liars to the extent that we attempt it. Every man has a point of view different from every other man, which is also changing more or less rapidly.

This is so by reason of the continual change in all the elements of value. Cost of material, cost and efficiency of labor, efficiency of superintendence, availability of specialists, as well as the valuators' knowledge or ignorance of these things, all affect value, and all are constantly on the move.

Actual investment is an element more or less known, and has some bearing, diminishing with time and increasing with knowledge of conditions at the time the investments were made; but actual investment

Mr. Dillman.

is the measure of value of nothing else. Why should it specially apply to public utilities? Why should an investor in a public utility be guaranteed against loss or deprived of unearned increment, any more than the purchaser of a farm?

Value of securities is an element to be considered, but is no proper measure of value. The market for securities is so easily manipulated that there is hardly anything more variable than stocks and bonds. Even without manipulation, the value of securities is only an expression of opinion of that part of the public making the investments or contemplating it. Public opinion, though seldom well expressed, is always wrong. It is not as far wrong as is possible to individual opinion, but it is never right.

Cost-of-Reproduction is an element to be considered. It is logically the best measure of value. Cost-of-Reproduction in present condition of parts being impossible, it becomes necessary to resort to Cost-of-Reproduction-New-Less-Depreciation, as the best method of approximating value. So this favorite method of Courts and commissions is founded on reason. After all, the final test of trust is reason.

A public utility is best operated as a monopoly, and generally is. So the value of the privilege, the franchise, may have a definite value. It may have cost something. It may be a contract that is worth something, though that something may be less definite than the value of physical property. To the extent that it has value, such should be added. This value is more or less tangible. When a franchise has cost nothing, is worth nothing, does not exist, or has competition, it is hardly an element of value.

Preliminary costs, water rights, power rights, promotion, administration, engineering, interest and taxes during construction, are all sufficiently tangible to be added to the above. They should certainly be added as legitimate elements of value. They can no more be fairly excluded than a pumping plant or a terminal or a sub-station.

Anything, in fact, that would cost something in replacement, should be considered and valuated, just as the physical parts are valuated at what they would cost at the time of valuation.

The sum of all the above is the value of the utility, when the utility performs its purpose and is not overbuilt. Every reader has some knowledge of cases where a railroad is constructed with insufficient traffic, a water-works with an insufficient supply, and all utilities with a dearth of customers. In these exceptional cases, the works are worth less than this sum. In no case, however, is the value greater than this sum.

This question of valuation is important to-day, and is growing. If the Society can reach a rational conclusion, the foundation of a great variety of correlative questions will have been settled. It is more important that the basis of valuation be fixed than that it be right.

Mr. Dillman.

If it can be fixed right, well and good, but it will be pretty near right now, and we need it fixed that other problems based more or less on valuation can be considered. So far as can be judged on the Pacific Coast, the Legal Profession is willing to adopt our conclusions if we conclude.

Valuing public utilities has developed a large and somewhat plausible school of "experts," whose efforts are to increase the above valuation by large amounts. Sometimes they have "delivered the goods." Demand, as usual, creates a supply. If they can "deliver the goods," there is a market for them, with fees in accordance.

The main argument is for a large amount for "going value" or "going concern" or "going concern value," which is variously defined, defended, and contended for.

If the valuations are made as above outlined, these intangibles are all covered. The valuation is made as a "going concern." Otherwise, the plant would have a second-hand and scrap value. So the value of "going concern" is entirely included, and is a very large part of the "value," as found above. If anything more is added for "going concern," it is a duplication.

The writer would make a distinction between depreciation and allowance therefor. Two points in depreciation are known: the start (100% value), and the finish (scrap value). As these, like other elements of value, are more or less (principally more) matters of opinion, it can be a matter of small moment, either to the utility or the public, what line is followed in making allowances for depreciation, provided such allowances are considered in rate-making.

No method for such computation will be in accord with the facts, so the Straight-Line Method is advocated, because of its simplicity. If any curve is used, the writer suggests the conic parabolic as being more likely to accord with the facts than the Sinking-Fund Method, and simpler to apply.

The writer would take issue with the Committee's recommendation that present prices and original conditions be used, and prefers present prices, and present conditions. These are better known, and the original conditions are generally a matter of hearsay. Similarly, whether the plant be constructed piecemeal or otherwise is irrelevant. Such may have resulted in economy instead of expense. Certainly, the method used makes no difference in service, or present cost, or depreciation, and, therefore, none in value. The time and the methods assumed in the appraisal should be entirely reasonable for the reproduction now.

The writer can see no reason for finding a different value for different purposes, provided the public service is the same. If other property is assessed for taxation at 60% of its value, 60% should be used for taxation of the utility, but the value should not be changed except on the assessor's books. So, too, portions not used or useful

Mr. Dillman.

might be excluded for rate-making purposes and be included in purchase or condemnation, but the same item in use has the same value for all purposes, and the value of the utility is the sum of the values of its parts.

Mr. Wheeler.

WALTER S. WHEELER, M. AM. SOC. C. E. (by letter).—The writer agrees with the Committee that "the inventory should be made in much detail and with much care in order to obtain the best results". Under the heading "Inventory" the Committee says:

"Take, for an extreme instance, the dredged channel of the Panama Canal leading from the deep water on the Atlantic side to a short distance beyond the shore line. The Annual Report of the Isthmian Canal Commission to June 30th, 1912, states that the geometrical quantity represented by the excavation of this channel to that date was 10 169 000 cu. yd., while the actual quantity taken out of the channel amounted to 22 886 000 cu. yd., an excess of 125 per cent."

Now the writer does not wish to criticize that statement, as he has personal knowledge that it is practically correct, even if he had never seen the Report of the Isthmian Canal Commission. However, he does wish to say that the statement as it stands is very misleading, and the Committee should not have used it without going into the reports more fully.

That report states also, that the unit cost of dredging those 22 886 000 cu. yd., taken as a whole, was $0.2412 per cu. yd., or $5 520 103.20 for the total cost.

The reports also show that the sea-going suction dredge, *Caribbean*, took out the most of that excess of 125%, which was silting (and could have taken it all out), at a cost of approximately 10 cents per cu. yd., that is, 12 717 000 cu. yd. at 10 cents equals $1 271 700.00 for the total excess. Subtracting this last amount from the total cost, we have, $4 248 403.20, which is the actual cost of dredging the original or geometrical quantity of 10 169 000 cu. yd. (within the limits as stated), a considerable portion of which was rock that had to be blasted and dredged at depths varying from 20 to 42 ft. below sea level, with dredges that could not operate in the roughest weather as could the *Caribbean*. This gives an excess of material of 125%, but only 30% in excess of cost.

Thus, on further examination, it is shown, in the case mentioned, that it is not such an extreme instance at all, and that it would have been much fairer, when taking quantity without cost into consideration, to have used the geometrical quantity represented by the excavation for the comparison, than to take the whole quantity excavated. All of which goes to show that the examination of this most important subject cannot be too thorough.

The importance that is given to the Court decisions by those discussing the Committee's report is interesting.

In closing his discussion,* Mr. Knowles says: Mr. Wheeler.

"Reservoirs, pipe sizes, * * *, all need to be planned in varying degrees for the probable needs of a number of years. This is but ordinary good business judgment, and the sooner we can get the Courts to recognize this principle the better for all."

On the same page, Mr. Leighton limits his discussion to citing a part of the discussion of Mr. Hazen and directly after that he cites an interesting Court decision which tends to disprove Mr. Hazen's part of the discussion, just as if the fact that the Court having said it was sufficient proof to be final without further discussion.

The writer is of the opinion that Mr. Stearns "strikes the nail on the head", when he says in his discussion:†

"There is no doubt that a Court is fallible, and that, in many matters, it is dependent on the testimony and arguments brought before it, but when an able Court, like the Supreme Court of the United States, composed of men who are able to take a broad view of matters which are presented to them, makes a decision to which it adheres consistently for many years, such decision should be deferred to * * *."

Mr. J. N. Dodd, in his discussion‡ states that if "80% of the estimated life of the main has expired at the date when the street was paved, only 20% of the added value due to the paving can be added to the capitalization of the company", which infers that if the main was put in directly before the paving was laid, the full value due to the paving should be added.

In most well-regulated cities the franchise ordinances require the companies to lay what mains they will need, or will probably need, for a number of years, in streets about to be paved, and in other cities where such conditions are not included in the franchise ordinances, the companies with keen business foresight will endeavor to do so. According to Mr. Dodd's reasoning, such companies should have the full increased value, due to the paving, added to the capitalization at once.

Those newly laid mains would cost practically nothing to maintain for many years to come, while the old mains of another company, the capitalization of which had been added to by only a proportion of the value due to the paving, would, at times, be leaking gas or water into the street, causing extra expense to the company for repairs, and annoyance to the public.

The estimated life of the mains for proportioning this increased value would be a very variable quantity, especially in cities where electrolytic action is at all active, and in such cases, the added value to the capitalization would, invariably, be too large.

---

* *Proceedings*, Am. Soc. C. E., May, 1914, p. 1386.

† *Loc. cit.*, p. 1402.

‡ *Loc. cit.*, p. 1380.

Mr. Wheeler.

Appeal to the Courts for damage from electrolysis is not always successful, due to the owner of the pipes not being able to prove whose electricity damaged them, especially where several electric companies are distributing in the immediate vicinity.

The owner of extra large mains, wisely put in before the new pavement was laid, should not have his property excluded because it is unused, or partly unused, as it is not only a benefit to the public not to have the new pavement torn up, but it may have been mandatory in his franchise ordinance. Also, his mains will deteriorate in value before they are used to their full capacity, and it certainly would be unjust not to allow him increased value due to the paving if his property was excluded on account of unusual size at the time of placing it.

However, in such a case, the writer is of the opinion that if the owner is allowed full value for the partly unused portion of his property, he should not be allowed increased value due to paving. Also, if the owner of the old mains below the new pavement had used ordinary business foresight, he would have renewed his mains before the pavement was put in, and thus saved himself most of the extra expense of tearing up and replacing the pavement for repairing leaks. In the latter case, the annoyance and extra expense to the public should be considered, and he should not be allowed increased value due to paving.

In many of the franchise ordinances granted for street railways in different cities, we find conditions that read somewhat as follows:

"The grantee, its successors or assigns, shall, from time to time, grade or regrade, pave or repave, * * * the right of way granted by this franchise, at the same time that the City shall grade or regrade, pave or repave * * * the adjoining portions of the street. The pavement between the rails and the tracks and for 2 ft. on either side thereof (the grantee's portion), shall be of the same general material as that of the adjacent portion improved by the City, and shall be maintained in an equally good condition as the City's portion."

In the franchise ordinances of the owners of mains and conduits, we find that the owner must raise or lower his property to conform to the new grades of the streets, but we seldom find a condition that requires him to pave and repave and maintain the pavement above his mains and conduits, except temporary openings for repairs, or when the pavement has been put down before the mains or conduits were laid.

If the owners of mains and conduits wish the full value due to the paving added to their capitalization, why not place the condition in future franchise ordinances, requiring them to pay the City for the paving of that portion directly above their mains and conduits, in proportion to the width of the latter, and for a few inches on each side thereof? In such a case there would be no question about adding the value of

the pavement to their capitalization. In most cases it would be impracticable to allow them to do their own paving, as such width would usually be small as compared to the width of the street railway paving, but it seems to the writer that if they desire it, they can be allowed to pay the City for such portion, and it would be just as reasonable as requiring the street railway to pave its portion. Mr. Wheeler.

After reading a number of the discussions on the Committee's report as regards railroads, the writer would suggest that we get away from the atmosphere of New York City and vicinity for awhile. Not but that the railroads having terminals in New York City are vastly important, but no one, so far as the writer has observed, has discussed railroads under this report with examples from any other standpoint. If there is true competition between such railroads, as most of the discussions infer, is not that in itself a regulator of rates until such competition ceases to exist?

The writer is of the opinion that valuation should be studied more thoroughly in the case of monopolies where there is no competition. Mr. Byers gives a very able discussion* from the standpoint of competitive railroads, but he overlooks the fact that some railroads are not competitive and that others serve large territories where there is practically no competition.

The examples which he gives of Eastern railroads, together with his statement that "probably without exception, every railroad serves some territories that are not served by any other railroad", gives one the impression that he considers all railroad business competitive with small exception. Take, for example, our transcontinental lines, and leaving out of consideration the through business from the Pacific Coast to Mississippi River points, do not these lines serve large territories without competition? Also, the railroads of Alaska which are not competitive, but whose original costs were enormous.

In referring to the equation:

$$\text{Tariff Rate} = \frac{\text{Fair Value} \times \text{Fair Rate of Return} + \text{Cost}}{\text{Output}},$$

Mr. Byers states that:

"It is clear that, in applying this equation to a gas plant or other utility of that sort selling one commodity, it is comparatively easy to solve, even though the various factors seem to be not of the most definite. When it comes to applying it to a railroad, the speaker must confess that he would like the Committee to go into a little detail as to the practical application of its theories, * * *."

As we go farther West to locations where competition in the railroad business is not so keen, the unknown quantities represented by

* *Proceedings*, Am. Soc. C. E., May, 1914, p. 1450.

Mr. Wheeler.

the thousands of outputs and tariff rates would be greatly reduced and the equation, therefore, would be easier to apply.

Mr. Byers evidently assumes that the equation could be used on the lines having the greatest competition, for he states:

"There is nothing said, in the Committee's list of principles, about the necessity for first valuing and establishing rates on all competing lines before attempting to value and establish rates on the line which is the immediate subject of the inquiry."

The valuing and establishing of rates on competing lines would certainly have to be considered in connection with the establishing of rates on any particular line in order to arrive at fair conclusions.

Another item that would warrant great consideration is where the bulk of the output is in one direction. A railroad located under these conditions would be justified in charging a higher rate than one located in territories where the cars would generally be loaded in both directions. For example, in years when the price of wheat was high, and the farmers along the Canadian Pacific Railroad were growing practically nothing but wheat, it was raised in such large quantities that the railroad could not take it all away, and the farmers burned much of it for fuel during the following winters. The cars carried wheat in one direction and returned empty.

HUACAL DAM, SONORA, MEXICO.

Discussion.*

BY MESSRS. CHARLES W. SHERMAN, M. M. O'SHAUGHNESSY, L. R. JORGENSEN, AND L. J. MENSCH.

Mr. Sherman.

CHARLES W. SHERMAN, M. AM. SOC. C. E. (by letter).—The writer has long felt that the arched dam is worthy of much greater attention than it has usually received. No one has ever shown how such a dam could fail, if the abutments were sound and the crushing strength of the arch and abutments was not exceeded; and, as a matter of fact, as noted by Mr. Hawgood, there does not appear to be any record of failure of a dam constructed on this principle.

The total number of dams in which dependence is placed on arch action for stability is so small that it seems desirable that a complete list be prepared. The author has overlooked several American arched dams, two of which rank next to the Bear Valley and Upper Otay in boldness, as measured by intensity of stress in the arch. The dams referred to are those at Lewiston, Idaho, and Winchester, Ky., built by William Wheeler, M. Am. Soc. C. E.

Table 9 contains a complete list of arched dams, as far as the writer has been able to ascertain, and includes data on ten dams not given in Table 1.

It is particularly interesting to note the test of a brick arch, 4 in. thick, with a radius of 58 ft. 1 in., comprising a facing wall of the Ithaca Dam, which occurred during the construction of the dam, as described by Gardner S. Williams, M. Am. Soc. C. E.† The arch was 52 in. high, with a clear span of 90 ft. and with a head of water

* This discussion (of the paper by H. Hawgood, M. Am. Soc. C. E., published in April, 1914, *Proceedings*, and presented at the meeting of May 20th, 1914), is printed in *Proceedings*, in order that the views expressed may be brought before all members for further discussion.

of 0.8 ft. over the top. According to the ordinary method of arch analysis, the stress in the arch at the base would have been 385 lb. per sq. in. Mr. Sherman.

Las Vegas Dam.—In 1910-11, the Agua Pura Company, of Las Vegas, N. Mex., constructed a concrete arched dam, 50 ft. high, to form a storage reservoir. It was designed to be increased in height to 95 ft., subsequently, and it was computed that, even if there should be no bond between the old and new work, and the full water pressure should be transmitted through the resulting joint, the maximum stress in the new work would not exceed 520 lb. per sq. in.

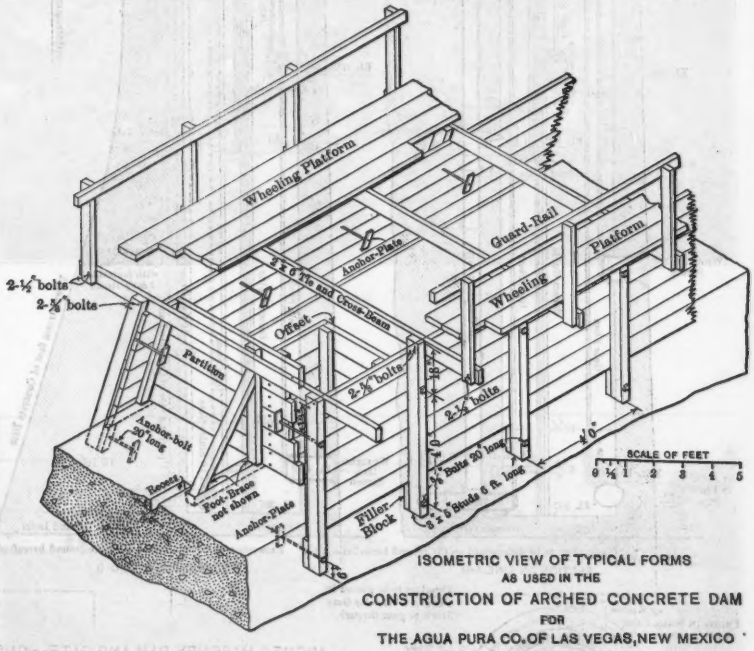

FIG. 18.

The design of this dam has been described briefly by the writer,* and its construction by William T. Barnes, M. Am. Soc. C. E.†

As the drainage area above the dam was very small, and a diversion ditch has been constructed by which the run-off in times of rain will be conducted out of the basin, it was thought possible to build the dam without a spillway, and to provide for the storage of water up to the level of the crest of the dam. The water is to be supplied to the

reservoir partly through a canal and partly through a pipe which also serves as an outlet. It was believed, therefore, that the likelihood of the water rising higher than was desired would be very small indeed, and that, in case of a cloudburst or other emergency causing the water to overtop the dam, no serious damage was to be apprehended. Fig. 18 is an isometric view of the forms as used in building the dam. Mr. Sherman.

In order to make possible the storage of water up to the level of the crest, without allowing waves to pass over, flash-boards have been provided. The flash-board pins were computed to yield and release the boards when the water reached a height of 2 ft. above the crest. The details of the flash-boards and of the hand-rail carried by the pins have been worked out so as to make it impossible for arch action to develop in the railing or boards.

The arrangement of the gate-house, Fig. 19, is believed to be novel, particularly in its compactness and the method adopted for screening the outlets at different depths by the use of a single section of screen.

Plate XXII shows the plan and section of the dam and gate-house, and the appearance of the structure when substantially finished is shown by Figs. 20 and 21.

The methods and costs of construction were stated by Mr. Barnes in the paper before referred to. It may be of interest to note here that the completed structure, including the gate-house, contains 2 703 cu. yd. of concrete, the average cost of which to the contractor was $7.09, and to the water company, $7.86. The excavations for the foundation amounted to 790 cu. yd. of rock and 245 cu. yd. of earth. The average cost of excavation to the contractor was $1.50, and to the water company, $1.43, per cu. yd.

M. M. O'SHAUGHNESSY, M. AM. SOC. C. E. (by letter).—The author's description of the Huacal Dam and the detail of the methods used in its construction, are to be greatly commended on account of the concise and thorough manner in which all elements relating to the project are discussed. Table 1, containing data on dams of this type previously constructed, is very complete, and the reasons advanced for adopting this type at this particular site deserve thoughtful consideration. With a very narrow gorge, foundation rock of excellent quality, and small property values below the site, the risk involved is perhaps justifiable; but with the menace following destruction by earthquake, doubtful characteristics of the foundation, or local weaknesses in the construction due to inferior material or workmanship, which evade the best inspection and supervision, it is very questionable whether it is good policy to take the risk of relying on a structure of such refined proportions, where a great calamity to life and property might follow from a failure. Mr. O'Shaughnessy.

In the case of the Upper Otay Dam, referred to by the author, of about 1 000 000 000-gal. capacity, which lies immediately above the

Mr. O'Shaughnessy.

Lower Otay Dam and Reservoir, of 13 000 000 000-gal. capacity, the writer was always impressed with the consequences to the structures lower down, which might follow a failure of the upper dam from a destructive earthquake. The lower reservoir, however, has a capacity of 13 000 000 000 gal., and is rarely more than half filled, so that there will always be a fair space to take care of the released volume in case of breakage, though a wave action might top the lower dam or crowd the spillway to its capacity.

In dam construction, engineers on the Pacific Coast are often compelled to adopt economies of design which older and richer communities can afford to reject, in other words, they are very often compelled to adopt boldness of design, which, under other conditions, they might not accept.

The cost of the Huacal Dam was $114 000, excluding water rights or reservoir site, and as the capacity is 2 700 acre-ft., the cost was $42 per acre-ft., which is very reasonable for a structure of this type, with a small reservoir basin and a limited water-shed. The concrete work in the structure must have been well done, as the leakage is only 6 000 gal. per 24 hours; and the precautions adopted by Mr. Hawgood to obtain a superior concrete mix are to be commended. In concrete for dam construction and hydraulic work, there is a modern tendency, even in some large works, to be rather slipshod in the methods, precautions, and proportions used, with the inevitable result of after consequences to the structure and damage to the reputation of the engineers.

The spillway provisions seem to be ample, but, even with a little topping of the main structure, injuries should not be feared, on account of the water-cushion provided at the base. A clearer account of the spillway gates would be appreciated. It was not until 5 years ago that a spillway was provided at the Upper Otay; water passed over the crest of that dam, and cut away some material at the foundation, but did not hurt the structure.

A recent inspection of the Lake Spaulding Dam showed a deflection in the center of 3½ in., when full. It will be interesting to note the deflections in the Huacal Dam.

Mr. Hawgood is to be thanked for writing a paper which is so complete and of such great value to those members of the Profession who are interested in structures of this particular type.

Mr. Jorgensen.

L. R. JORGENSEN, ASSOC. M. AM. SOC. C. E. (by letter).—For such a site as that shown on Fig. 5, there can be no doubt that an arch dam is the safest and cheapest type that could be put in. The (approx.) box canyon in which the 100-ft. dam is located is only a little more than 100 ft. wide at the crest. This narrowness of the canyon allows the use of a short up-stream radius, which is the main requirement for high economy in the arch dam. The axial

Mr. Jorgensen.

stresses chosen by Mr. Hawgood are very conservative, as they ought to be for a structure having such fairly slender proportions as the Huacal Dam. The writer does not quite see the use of the vertical reinforcement in an arch dam of the Huacal type, but, after all, this steel is a small item.

It would be better if engineers in general referred to dam faces as the up- and down-stream faces instead of front and rear faces, as this latter definition is not as clear as the former and is often used inconsistently.

Mr. Hawgood has built a very good substantial structure and need not make any excuses for putting in an arch dam. An engineer who would recommend any other type for the site in question would have a hard time finding enough excuses to justify such a decision.

With the exception of the formula giving the down-stream deflection of the crown of the dam under load, all other formulas used in arch dam design, while they are not absolutely accurate, are as accurate as those ordinarily used in the field of practical mechanics.

In dam design the load is definitely known; it is not, however, definitely known, where this load applies itself, unless the up-stream face is provided with a fairly water-tight skin, such as a plaster put on with a concrete gun. This is one reason why dams having a slender section ought not to be stressed (unit stress) as high as arch dams having a heavier section.

In the formula for the deflection of the crown the modulus of elasticity of the concrete appears. Some value for this has to be substituted in the formula, and that is where the biggest assumption in dam design is apt to be made.

To know, beforehand, what the deflection of the dam, when loaded, is going to be, is of small real importance, and if it turns out to be different from the calculated deflection, it is thereby indicated that the modulus of elasticity of the mass of concrete is different from the assumed one. The modulus of elasticity appears in other formulas, but in such a way that it cancels, and, therefore, no assumptions as to its actual value need be made.

According to the writer's view, an arch dam can be calculated as accurately as most structures, and when it is considered how far from its crushing strength the material is ordinarily working, such a structure should be readily accepted by all engineers as the safest, as well as the cheapest, that can be built in such a place as that described by Mr. Hawgood.

The automatic overflow gates provided for the Huacal Dam are very simple and evidently effective, and undoubtedly will give good satisfaction.

Mr. Mensch.

L. J. MENSCH, M. AM. SOC. C. E. (by letter).—The Huacal Dam and the many others mentioned in this paper should convince the most skeptical engineer that arched dams with cross-sections much lighter than those of gravity dams, have a fair factor of safety. None of these structures ever failed or showed larger or more numerous cracks than those found in gravity dams. Arched dams, being considerably cheaper than gravity dams, would be often used in place of earthen dams but for the fact that engineers have no confidence in the rather primitive, although evidently adequate, method by which the pioneer builders determined the cross-section of these structures. Engineers are afraid that some hidden defects exist in these dams, for which they cannot satisfactorily account by theory and for which they do not care to become responsible.

The objections to the assumption that arched dams act like cylinders subjected to external pressure are the following:

First.—These dams are arches fixed at the abutments, and like other arches are subjected to stresses due to the shortening of the arch, change of temperature, and shrinkage and swelling of the concrete. When the reservoir is filled, the swelling of the concrete and the fall of temperature from the original temperature of setting counteract each other to a great extent, and only in case of the reservoir being empty there may exist the most unfavorable condition of a fall of temperature and shrinkage of concrete acting together with the tendency to produce cracks. It can be shown that these stresses are of importance only in the upper half of the dam.

Second.—It is evident that these dams act partly as gravity structures, and the unknown extent to which they act as such is the main objection of thoughtful engineers to this type of dam. In the discussion* on the paper by G. N. Houston, M. Am. Soc. C. E., on the Halligan Dam, the writer has shown that the greatest portion of the water pressure is resisted by gravity action. He is now obliged to confess that he overlooked an important point. He assumed that the dam acted as a gravity structure entirely within the limit of ordinary beam action, following Hooke's law. This is not the case in masonry dams after the resultant of forces strikes the base outside the middle-third, or in a reinforced structure after the stresses in the steel bars reach the elastic limit. In both cases after cantilever action is nearly exhausted we have the condition of the dam being rather hinged at the bottom than immovably fixed, as formerly assumed by the writer, and if this condition is assumed, theory gives results which agree exceedingly well with practice.

It is an acknowledged and very plausible law of Nature that, among all possible deformations which a structure subjected to exterior

* *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 185.

forces can perform, deformation will take place, which will make the work of the internal forces a minimum. Mr. Mensch.

It can be proven that the work of compressing the structure as an arch (as long as the water level remains not higher than about 30 to 40% of the total depth of the water above the base of the dam) is much greater than that necessary to deflect the structure as a cantilever, hence gravity action must be the preponderant influence by which the stresses at the bottom of the dam are governed when the reservoir is about half full.

If, instead of an arch, we assume a complete cylinder like a water tank, it follows that the walls of the tank cannot move, even if set on a frictionless base, before the cantilever action is exhausted. The futility of all devices which were ever patented to disconnect walls of tanks from the base is thereby shown.

It can be shown that in all arched dams, with the possible exception of the Zola Dam, the lower portion of the structure of a height of about 5% of the total depth of water is strained far beyond anything possible in a gravity structure, yet no harm can come to the dam, because when gravity action ceases, arch action takes its place, and while probably every gravity dam would fail should the water rise to twice the height of the dam, some of the arched dams mentioned by Mr. Hawgood have a factor of safety of three.

The author thinks that both the rock at the base and at the abutments of the dam moves in accordance with the dam, and hints that this may explain his success. Any rock which would allow such movements would be entirely unsuitable for an important arch structure, and to assume that a very much larger mass of rock than the mass of the dam allows anything but infinitesimal deformations, is out of the question.

MEMOIRS OF DECEASED MEMBERS.

NOTE.—Memoirs will be reproduced in the volumes of *Transactions*. Any information which will amplify the records as here printed, or correct any errors, should be forwarded to the Secretary prior to the final publication.

HOWARD ELMER ARTHUR, M. Am. Soc. C. E.*

DIED APRIL 19TH, 1914.

Howard Elmer Arthur was born at Warren, Ohio, on January 26th, 1872. He was educated in the public schools of Washington, D. C., and studied architecture for one year in the office of Messrs. Smithmeyer and Pelz of that city.

In August, 1891, Mr. Arthur came to New York City and entered the office of the Jackson Architectural Iron Works, where, for 5 years, he was engaged in detailing and checking the steelwork for office buildings, etc., erected by that firm. In August, 1896, he went to Paterson, N. J., where he was employed by the Passaic Rolling Mill Company, detailing and checking trusses, plate girders, etc.

In April, 1897, Mr. Arthur returned to New York City, where he was engaged, until December, 1898, with the firms of Cooper and Wigand and Lewinson and Just, in detailing and checking, and in charge of construction work. He resigned his position with the latter firm to go with the Union Bridge Company, at Athens, Pa., on detailing and checking and in charge of work. Slackness of work at the Union Bridge Company's plant caused Mr. Arthur to return to his former position with Messrs. Lewinson and Just in September, 1899, where he remained until March, 1900, when he went to St. Louis, Mo., with the Koken Iron Works, as Assistant Engineer. While in this position, he had charge of the construction of the Frisco Building, the Mississippi State Capitol Building, mining and mill buildings, tanks, etc. In 1902, Mr. Arthur was transferred to the Contracting Department of the American Bridge Company as Contracting Agent, and was also engaged on designing and estimating the cost of steel structures.

In September, 1904, he went to Dallas, Tex., as Chief Engineer of the Mosher Manufacturing Company, in which position he designed and estimated the costs for steel construction for various shops and buildings at Dallas and Houston, churches, highway bridges, tanks, domes, etc., as well as the Grand Stand at the State Fair Grounds at Dallas, which latter has been described by Mr. Arthur.†

In October, 1911, in order that his child, who was seriously ill, might receive proper medical treatment, Mr. Arthur returned to New

* Memoir prepared by the Secretary from information on file at the Society House.

† *Engineering News*, Vol. LX, 1908, p. 208.

York City. He entered the office of Olaf Hoff, M. Am. Soc. C. E., and, under Mr. Hoff's direction, made the drawings and calculations for the City Art Bridge from Fortieth to Forty-second Streets, connecting to the Grand Central Station, and various other constructions. He remained with Mr. Hoff until March, 1912, when, owing to failing health, he was compelled to resign. He spent the next two years in Vermont, Tryon, N. C., and the Catskill Mountains, in a vain endeavor to improve his health, but died of tuberculosis at Big Hollow, N. Y., on April 19th, 1914.

On March 17th, 1905, Mr. Arthur was married to Miss Nettie Thomas, who survives him.

Mr. Arthur was elected a Member of the American Society of Civil Engineers on November 8th, 1909.

JAMES JOSEPH FERRIS, M. Am. Soc. C. E.*

DIED MAY 15TH, 1914.

James Joseph Ferris, the son of John and Mary (Harrington) Ferris, was born in Listowel, County Kerry, Ireland, on September 17th, 1860. When he was five years of age, his family came to the United States and settled at Carmel, Putnam County, New York, where they lived for six years, until ill-health and business reverses caused their return to Ireland. Mr. Ferris' early education, started at Carmel, was completed in Ireland, and, after leaving school, he helped his father, who was the manager of a large estate.

After a few years at farm work and at the age of twenty, Mr. Ferris returned to the United States and settled in Jersey City, N. J. He entered the employ of D. S. Cofrode and Company, as Timekeeper, and, subsequently, as Foreman, on important bridge work and other heavy railroad construction in Maryland, Pennsylvania, and Virginia.

Early in 1886, during the settlement of the estate of this firm, he was made Superintendent by the executors, and was in charge of all the work being done by the firm. When a re-organization was effected in 1888, under the firm name of Sandford and Stillman Company, Mr. Ferris was appointed General Superintendent, and held this position until 1902, when the firm was re-organized and became known as The F. M. Stillman Company, Mr. Ferris remaining as General Superintendent. In 1911, the firm was again re-organized under the name of Stillman-Delehanty-Ferris Company, Engineers and Contractors, and Mr. Ferris became Vice-President and Chief Engineer, in charge of all engineering and outside work. About a year ago (1913), he became President of the Company.

* Memoir prepared by Louis Chevalier, Assoc. M. Am. Soc. C. E.

Mr. Ferris' engineering education was obtained at Cooper Union Institute in New York City, and through constant home study. He was a keen observer, possessed a wonderful memory, and qualities for thoroughness, ready debate and argument, and was of a most genial and happy nature. Accustomed to directing the labor of large numbers of men, he had fine tact, most courteous manners, and, in a very high degree, the power to command loyal service and friendship from others.

He was in charge of various parts of the construction of the Pennsylvania Railroad Company's train-shed and office building, and the ferry slips and sheds at Jersey City, and directed the work of the grade crossing elimination for the same railroad through that place. He was also in charge of the construction of the roundhouse and yards of the New York, Susquehanna and Western Railroad, at Shadyside, and of various other work about New York Harbor, notably the sinking of the shafts at Washington Street and at Exchange Place, in Jersey City for the tube elevators for the Hudson and Manhattan Railroad Company, and the construction of the Hackensack River Turnpike Bridge.

In June, 1913, Jersey City adopted a Commission form of Government, and Mr. Ferris was signally honored by being elected a member of the first Board to govern its civic affairs. He was selected to take charge of the Department of Streets and Public Improvements, and during the past year he had brought his Department to a high state of efficiency, his most notable achievement being a thorough cleaning up of the City's water supply on the Boonton water-shed.

Mr. Ferris died suddenly on May 15th, 1914. He was a thorough and painstaking engineer, an exceptionally devoted student, was esteemed and admired by all who knew him, a faithful friend, a devoted father, and a good citizen.

In 1888, he was married to Miss Bridget Ryan, of Baltimore, Md., who, with five sons and three daughters, survives him.

Mr. Ferris was elected an Associate of the American Society of Civil Engineers on July 10th, 1907, and a Member on September 3d, 1912.

WEBSTER GAZLAY, M. Am. Soc. C. E.*

DIED FEBRUARY 17TH, 1914.

Webster Gazlay, was born in Louisville, Ky., on February 17th, 1862, and given the name of "Webster" in recognition of his father's admiration for the great statesman. His surname has come through mutations from Gazeley, Gazelle, Geasley, and Gaselee, of early Eng-

* Memoir prepared by J. M. Johnson, M. Am. Soc. C. E.

land. For the past 400 years, Judges of the name of Gaselee have sat on the King's Bench, in England, and their decisions are still quoted in English books of law. A Judge Gaselee was Dickens' prototype, it is said, for "Judge Stareleigh" in Pickwick's famous breach of promise suit.

Mr. Gazlay's mother was a Wheeler, of Virginia ancestry, Chaplines and Claibornes blending. On her maternal side, John Randolph, of Roanoke, was a kinsman.

In 1715 (Old Style) the English progenitor of the family in America settled in the State of New York, and his son, John Gazlay, was a member of the Continental Congress. Webster Gazlay's father, Addison M. Gazlay, was born in the valley of the Unadilla River, in Central New York, went to Kentucky in his early manhood, and for many years was a leading commercial lawyer at the Louisville bar.

In spite of the marked inclination in the family to the pursuit of law, Mr. Gazlay early manifested such a love and aptitude for mathematics, that he easily stood at the head of his classes in such studies. This passion for mathematical investigation, undoubtedly influenced his choice of a profession and determined the precision of thought and act and the exactness in expression and language, that were matters of comment and banter among his intimate friends.

He was graduated from the Louisville Male High School in 1881, and, the death of his father preventing the further prosecution of his technical studies, he accepted a position as Draftsman in the office of the Chief Engineer of the Louisville and Nashville Railroad, where he remained until May, 1883.

After leaving the Louisville and Nashville Railroad Company, he was appointed Assistant to the late Charles Hermany, Past-President, Am. Soc. C. E., and was engaged on the construction of water-works at Frankfort, Ky., and on surveys, plans, etc., for a proposed reservoir for Nashville, Tenn.

On the completion of these projects, he became Assistant Engineer on the Louisville Southern Railroad (now a part of the Southern Railway System), and was in charge of a residency during the construction of that road.

In 1888, Mr. Gazlay accepted a position, as Assistant Engineer, with the Louisville Water Company, later becoming Assistant to the Chief Engineer, during the construction of a new pumping station and an extensive system of filters; he remained in this position until 1905, resigning at that time to become the Vice-President and Engineer of the National Concrete Construction Company, a contracting firm with its principal office at Louisville, Ky.

In 1906, he again returned to the Louisville Water Company as Associate Engineer, and retained this position until the completion of the filter plant in the Fall of 1909. In accepting his resignation,

the Water Board passed the following resolution to be recorded in its Minutes:

"To his intelligence in conception, vigor in execution, and tireless energy in the carrying on of the work, is due, in large measure, the successful completion of the great enterprise to which he has devoted himself."

Mr. Gazlay was married on November 7th, 1906, to Miss Lida Hampton, of Louisville, Ky., who, with three children, Webster Gazlay, Jr., Lida Hampton Gazlay, and Sallie Josephine Gazlay, survives him.

Mr. Gazlay was a man of high ideals and thoroughly in love with his Profession. All his concepts were strong and clear, touched in a great degree with that light and leading which humanity is wont to term genius. His standard condemned anything less than the wholly clean way of honesty and truth, and permitted no compromise where the facts were clear and plain. To his many friends, his untimely passing away is a source of great sorrow, but they have the consolation of knowing that it has been their privilege to work and walk with a man fashioned well and truly in the image of his Maker.

He was one of the original members of the Engineers and Architects Club of Louisville, Ky., and was always placed on committees where important and efficient work was demanded.

Mr. Gazlay was elected a Member of the American Society of Civil Engineers on June 7th, 1905.

WILLIAM AUGUST HUNICKE, M. Am. Soc. C. E.*

DIED MARCH 9TH, 1914.

William August Hunicke was born at St. Louis, Mo., on February 23d, 1875. He attended the public schools until 1889, when he was sent to Germany where he studied for three years. On his return to St. Louis, he entered Washington University, from which he was graduated in 1897, with the degree of B. S. in Civil Engineering.

His first employment was with Robert Moore, Past-President, Am. Soc. C. E., and the late J. B. Johnson, M. Am. Soc. C. E., after which he spent five years with the Mexican Central Railroad, in charge of the location and construction of various branch lines of that Company. Returning to St. Louis, he was placed in charge of the Washington University buildings and the laying out and improvement of the University grounds.

Mr. Hunicke was Assistant Engineer of the St. Louis Terminal Railroad during the time that Mr. Taylor was Chief Engineer, and in that capacity had charge of the relaying of the track in the tunnel,

* Memoir prepared by Leo C. Dziatzko, Esq., Webster Groves, Mo.

which work had to be accomplished without interference with the traffic. His next work was the location and construction of the extension of the railroads owned by the Sligo Furnace Company in Missouri.

From 1909 to 1911, he was Chief Engineer and Superintendent of Construction of the Apalachicola Northern Railroad, locating and building that road from Apalachicola to Jacksonville, Fla.

From 1911 to 1913, he was Superintendent of Construction for the English Syndicate in Cuba on various extensions of its roads, returning to St. Louis in August, 1913, to become Assistant Operating Engineer of the Missouri Pacific Railroad, which position he held at the time of his death.

Mr. Hunicke was a member of the Engineers' Club of St. Louis, the Railway Club of St. Louis, and the Missouri Athletic Club where he made his home, enjoying its comforts and environments. He was one of those who perished in the fire which destroyed the building on March 9th, 1914.

He was one of the best posted authorities on railroad location, construction, and valuation, and acted as Consulting Engineer on valuation work for a number of the smaller railroads of the South. Beloved by his friends, his was a life well spent in constructive work, and those who knew him well cherish his memory.

Mr. Hunicke was elected an Associate Member of the American Society of Civil Engineers on March 2d, 1904, and a Member on January 7th, 1913.

THOMAS HUMRICKHOUSE JOHNSON, M. Am. Soc. C. E.*

DIED APRIL 16TH, 1914.

Thomas Humrickhouse Johnson was born at Coshocton, Ohio, on January 12th, 1841. His parents, William Kerr Johnson and Elizabeth (Humrickhouse) Johnson became residents of Coshocton in their youth, during the first quarter of the last century.

William Kerr Johnson was born in Dungannon, County Tyrone, Ireland, of Scotch-Irish parentage, in 1809, and, while yet a boy, came to America with his brothers, residing first in Baltimore and moving West, in 1821, to the Village of Coshocton.

Elizabeth Humrickhouse was a descendant of a Prussian family which emigrated to America from the Duchy of Hesse Darmstadt in the early part of the 18th century, settling first at Bethlehem and Germantown, Pa., and at Hagerstown, Md. From Hagerstown, Peter Humrickhouse, the father of Elizabeth, moved West, finally settling in Coshocton.

* Memoir prepared by J. P. Snow, J. C. Bland, and R. Montfort, Members, Am. Soc. C. E.

Mr. Johnson's early education was under the tutelage of the Rev. William E. Hunt, then pastor of the Coshocton Presbyterian Church, under whom he was fitted for college.

In 1858 he entered old Jefferson College, at Canonsburg, Pa., and after three years was graduated at the age of twenty years, with the degree of Bachelor of Arts, in the class of 1861. On account of his unusual proficiency in mathematics, the degree of Master of Arts was conferred on him in 1866 by his Alma Mater, and in 1911 the degree of Doctor of Science by Washington and Jefferson University, the successor to the former colleges of Washington and Jefferson.

On graduation Mr. Johnson entered the employ of the Pittsburgh and Steubenville Railroad, of which his father was a director, as Rodman; and in 1863 he became Assistant Engineer in the construction of the Steubenville Bridge over the Ohio River. From 1867 to 1869 he served as Assistant Engineer on general work on the Pittsburgh, Cincinnati and Chicago Railway, from 1869 to 1871 on the construction of the Chartiers Railway, and in 1871 was transferred to Richmond, Ind., where he was engaged in the erection of the passenger station at that place until May 31st, 1872. From that date until March 1st, 1873, he served the Company in the general work along its lines, and then began the erection of the depot at Columbus, Ohio. On the completion of this work, in 1875, he was again transferred to Indiana, and throughout that year was in charge of construction of the Vincennes Engine House and Richmond Shops.

In the latter part of 1875 he severed his connection with the railroad and opened an office in Columbus, Ohio, for architectural work, and thereafter until March, 1883, was engaged as Chief Engineer in the construction of the present State Capitol at Indianapolis.

In 1883 he again entered the service of the Pittsburgh, Cincinnati, Chicago and St. Louis Railway, as Principal Assistant Engineer, which position he occupied until 1896, when, on the death of M. J. Becker, Past-President, Am. Soc. C. E., he was appointed to the position of Chief Engineer of the Southwest System. In 1901 he became Consulting Engineer for all Lines West of Pittsburgh, a position which he held until January, 1911, when he reached the age (70 years) of automatic retirement.

The services of Mr. Johnson were considered so valuable by the management of the Pennsylvania Railroad that the positions of Chief Engineer of the Pittsburgh, Chartiers and Youghiogheny Railroad, the Chartiers Southern Railway, and Special Consultant for the Pennsylvania Lines were created for him. This procedure, which is without precedent in the history of the Pennsylvania System, constitutes a striking tribute to his capacity and worth. It is a tradition among the Pennsylvania men that no subject was ever broached to him which failed to elicit information to the point and offhand.

In addition to his regular duties, his advice and counsel were frequently sought, and highly valued in cases where expert judgment

was required in difficult constructions, and in cases of adjustment between parties with opposing interests.

Mr. Johnson found especial enjoyment in association, not only with his fellow-engineers, but with all men of learning, and to that end he accepted many invitations to membership in scientific bodies. Besides membership in the American Society of Civil Engineers, he was a member of the American Railway Engineering Association; the American Society for the Advancement of Science; the American Society for Testing Materials; the American Forestry Association, and the Engineers Society of Western Pennsylvania. He was a member of the Rail Committee of the American Railway Engineering Association, of the Special Committee on Valuation of Public Utilities, of the American Society of Civil Engineers, and of the Rail Committee of the Pennsylvania System.

Of several of these societies he has at times been on the board of officers, and has served them on committees and as a delegate to various congresses. The Engineers Society of Western Pennsylvania is especially indebted to him, not only as an active officer, but as an adviser and mentor in times of stress, and as one ever ready to carry the burden of unusual activities and grave responsibilities whenever the needs of the society called him.

He was a valued contributor to the publications of many of the associations of which he was a member. To the American Society of Civil Engineers he contributed a notable paper "On the Strength of Columns; Discussing the Experiments which have been Accumulated, and Proposing New Formulas,"* and discussions on the cause and prevention of decay of building stone; a formula for the strength of columns; Progress report of Special Committee on Steel Columns and Struts; railway bridge designing; stresses in railway bridges on curves; and ventilation of tunnels. His paper and discussion on the Strength of Columns brought out the famous straight-line formula which he demonstrated to be the tangent and rational extension of Euler's curve. His discussion on the ventilation of tunnels was the result of his translation of a work by the Italian Government on tunnel ventilation, an abstrusely mathematical treatise which Mr. Johnson translated with the aid of an Italian dictionary and grammar in combination with his extraordinary mathematical ability.

He was 61 years of age when he translated this work, and when one of his engineer friends remarked on his industry and courage in undertaking such a task, he pointed to a page of the work and asked, "what constitutes the principal part of that page?" The friend answered, "mathematical expressions." "Yes," said Mr. Johnson, "a universal language."

In 1868 Mr. Johnson married Miss Martha E. Patterson, of Steubenville, Ohio, who survives him with two daughters, Misses

* *Transactions*, Am. Soc. C. E., Vol. XV, p. 517.

Bessie and Margaret Johnson, and one son, William K. Johnson, who is an attorney at law in Pittsburgh, Pa.

As a man, Mr. Johnson's notable characteristics were: perfect sincerity, single-mindedness, consideration for others, kindliness, charity, and a constant readiness to help others; and his utter uncomplaining, even in the hour of death. His vast fund of well-ordered knowledge was always at any one's command; and the younger men went to him for advice, counsel, and help as freely as a child to its father.

John Henry Newman says:

"The true gentleman carefully avoids whatever may cause a jar or a jolt in the minds of those with whom he is cast; all clashing of opinion or collision of feeling, all restraint, or suspicion, or gloom, or resentment; his great concern being to make every one at their ease and at home. He has eyes on all his company; he is tender toward the bashful, gentle toward the distant, and merciful toward the absurd; he guards against unreasonable allusions, or topics that may irritate; he is seldom prominent in conversation and never wearisome. He makes light of favors when he does them and seems to be receiving when he is conferring. He never speaks of himself except when compelled; never defends himself by a mere retort; he has no ears for slander or gossip; is scrupulous in imputing motives to those who interfere with him, and interprets everything for the best. He is never mean or little in his disputes, never takes unfair advantage; never makes personalities or sharp sayings for arguments or insinuates evil which he does not say out. * * *

"He is patient, forbearing, and resigned, on philosophical principles; he submits to pain because it is inevitable; to bereavement because it is irreparable, and to death because it is his destiny."

Such a man was Thomas H. Johnson.

Mr. Johnson was elected a Member of the American Society of Civil Engineers on September 5th, 1877, and served as a Director during the years 1900, 1901, and 1902.

NATHANIEL TURNER, M. Am. Soc. C. E.*

DIED JANUARY 19TH, 1914.

Nathaniel Turner was born in Scituate, Mass., on March 27th, 1861, and was educated at the public schools of that place, and at Bingham Academy.

Leaving home at the age of nineteen, Mr. Turner went West and began work as a Rodman on the location of the Milwaukee, Lake Shore and Western Railroad, in Wisconsin, in 1880. In 1881, he was made Transitman on the same work.

In 1882, Mr. Turner left the employ of the Milwaukee, Lake Shore and Western Railroad and went to Mexico where he was appointed

*Memoir prepared by the Secretary from information on file at the Society House.

Levelman on the line of the Mexican National Railway then being constructed between Laredo and the City of Mexico. He remained with this Company until 1888, having served as Transitman, Resident Engineer, and Bridge Engineer, respectively. In 1884, he was employed on trigonometrical surveys of large land areas in the State of Coahuila, Mexico.

In 1888, Mr. Turner was appointed Bridge Engineer and in 1889 Locating Engineer on the Monterey and Mexican Gulf Railway, then building between Monterey and Tampico, under Mr. William H. Wentworth, Chief Engineer. In 1890, he was made Principal Assistant Engineer in charge of construction, remaining in that position until 1892, when he resigned to become Chief Engineer of the Matehuala Porvenir Railway. He also served as Locating Engineer on the Gulf and Pacific Railway. In 1893, he was appointed Chief Engineer of the Monterey and Mexican Gulf Railway, in which position he remained until 1897.

From 1897 to 1901, Mr. Turner was engaged in the private practice of engineering. In the latter year he was appointed Superintendent of Construction of the Monterey Steel Works, a $10 000 000 plant. On the completion of this work in 1904, he again returned to private practice for a year, at which time he went to Matehuala, San Luis Potosi, as General Superintendent of the Matehuala Smelter and Water-Works.

On account of ill-health, Mr. Turner resigned this position in 1908, and retired from active business. He owned a ranch in Tamaulipas and oil investments near Tampico, and devoted his time to these interests, making his home in Monterey. He died of heart disease on January 19th, 1914, and was buried in the Carmen Cemetery, at Monterey.

In 1885, Mr. Turner was married to Elizabeth Luella Donaldson, of Rock Island, Ill., who, with one daughter, survives him. He was one of the best known and best loved Americans in Northern Mexico, and had served as President of the American Colony in Monterey.

Mr. Turner was elected a Member of the American Society of Civil Engineers on March 6th, 1895.

GEORGE JOHN COUCHOT, Assoc. M. Am. Soc. C. E.*

DIED MAY 3D, 1914.

George John Couchot was born in Paris, France, on August 23d, 1874. In October, 1887, he came to the United States, going to Oakland, Cal., where he attended the High School.

After a course in an Engineering School, Mr. Couchot, in October,

* Memoir prepared by the Secretary from material on file at the Society House, supplemented by information supplied by Maurice C. Couchot, M. Am. Soc. C. E.

1892, was engaged by the City Engineer of San Luis Obispo, Cal., on transit work. In March, 1893, he went to the Fulton Iron Works, in San Francisco, as Mechanical Draftsman, remaining in that position until August, 1894. From April to December, 1895, he was employed by the State Harbor Commissioners of California, leaving to go with the Western Sugar Refining Company, with which Company he remained until December, 1896.

From January to April, 1897, Mr. Couchot was employed as Draftsman in the office of Mr. J. C. H. Stut, Mechanical Engineer, and was engaged on the design and construction of the steel frame building for the Western Beet Sugar Factory, at Watsonville, Cal., until August of the same year. He then entered the service of the Fulton Iron Works as Mechanical Draftsman, which position he held until August, 1898.

From October, 1898, to March, 1900, Mr. Couchot was employed as Mechanical and Ship-Building Draftsman by the Union Iron Works, of San Francisco, but resigned to accept again a position with the Fulton Iron Works. In March, 1901, he was appointed Assistant Engineer of the Western Sugar Refining Company, in charge of the design and construction of all that Company's improvements, buildings, machinery, etc.

In February, 1905, he was employed, on the design of steel structures, by Maurice C. Couchot, M. Am. Soc. C. E., Consulting Engineer, with whom he remained until June, when he was appointed Draftsman in the office of the City Engineer of San Francisco. Mr. Couchot retained this position until September, 1907, when he became connected with the firm of Couchot and Thurston, Consulting Engineers, on the design of structures. In August, 1908, he returned to the City Engineer's office where he remained as Chief Draftsman and Assistant Engineer in charge of some of the sewer design and construction, until his death on May 3d, 1914, after an operation for appendicitis.

Mr. Couchot was held in high esteem by all who came in contact with him. His wife and a young son survive him.

Mr. Couchot was elected an Associate Member of the American Society of Civil Engineers, on May 3d, 1910.

ALBERTO DE LA TORRE, Assoc. M. Am. Soc. C. E.*

DIED OCTOBER 5TH, 1912.

Alberto de la Torre, the son of Demetrio de la Torre and Maria Josefa Umaña, was born in Tocaima, Colombia, on August 6th, 1876. He received his elementary education in his native country, and in June, 1889, was sent to the United States to begin the study of Civil

*Memoir prepared by Mr. Diodoro Sánchez, President of the Colombian Society of Engineers, Bogota, Colombia, supplemented by information on file at the Society House.

Engineering at Rensselaer Polytechnic Institute. He was graduated in 1897, with the degree of Civil Engineer, and returned to Colombia to devote himself to the practice of his profession.

Mr. de la Torre was engaged in private practice in Bogota from March, 1897, to August, 1898, his work consisting of surveying and general engineering. In September, 1898, he was appointed Assistant Engineer of Maintenance of Way on the Ferrocarril de la Sabana, but resigned this position in December, 1898, and engaged again in surveying and general engineering practice.

In April, 1899, Mr. de la Torre accepted the position of Assistant Engineer on the location of the Girardot Railway (now the Colombian National Railway), and remained in this position until the completion of the location to San Joaquin, in July, 1899, when he was appointed Assistant Engineer, under Mr. T. B. Nowell, on the location of the Dorada Railway Extension to the Port of Cambao.

From October, 1899, to April, 1901, he was again engaged in the private practice of surveying and architectural work, and from April to October, 1901, was employed temporarily as Engineer of Way Works on the Dorada Railway.

He was employed as Assistant Engineer on the location and construction of the Girardot Railway from October, 1901, to May, 1904, and, during this time, also had charge of the construction of several private residences, and made the surveys for a cart road on a private estate.

From May, 1904, to July, 1905, Mr. de la Torre was engaged as Engineer and partner of the contractor, on the construction of 2 km. of the Girardot Railway, and from July to December, 1905, he was employed as Assistant Engineer on surveys and estimates for the reconstruction of the Cambao Road. He was afterward appointed by the Government of Colombia to direct the work on the Central Road, between the Puente del Común and Chocontá. In 1908, he again entered the employ of the Girardot Railway Company, being engaged on the construction of the last sections between Zipacón and Facatativá. He was then appointed Resident Engineer in charge of the last section from Girardot to Juntas de Apulo, which position he held until July 1st, 1912.

Mr. de la Torre was a member of the Colombian Society of Engineers, and the following is a translation of part of an obituary notice which appeared in the November, 1912, issue of the *Anales de Ingenieria*, the official organ of that Society:

"His constant labor for a dozen years, and his continual battle with the inclemencies of our tropical climate, destroyed his energy and weakened his physique to the extent of bereaving his country and his friends of a noble young life which had already rendered distinguished professional services."

Mr. de la Torre was elected an Associate Member of the American Society of Civil Engineers on October 3d, 1906.

WATER SUPPLY OF THE SAN FRANCISCO-OAKLAND METROPOLITAN DISTRICT.

By H. T. Cory, M. Am. Soc. C. E.

To be Presented November 4th, 1914.

Synopsis.

This paper deals particularly with the municipal water supplies, present and future, of the cities around the Bay of San Francisco, and incidentally of the so-called Hetch Hetchy project, for which Congress recently granted the necessary permits.

First, a detailed study is made of the population growth of the San Francisco-Oakland Metropolitan District and its several subdivisions. The conclusions reached are that, probably:

The East Bay portions will pass San Francisco proper in population, and to a greater extent in water requirements, in about 20 years;

The next census will show the entire district second to Greater Los Angeles; and that,

After a normal growth for two or three decades, Greater San Francisco-Oakland, and especially the East Bay district, will, for a few decades, grow very rapidly.

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

Then follows a brief description of existing systems and statements of their possible full development.

The question as to whether the Bay cities need and can afford a distant supply in the immediate future is then discussed.

Four or five decades hence, with the utmost co-operation of all interests, local supplies must be supplemented by water brought in from a distance.

The last two parts deal, respectively, with the considerations governing a wise choice of such distant supply or supplies, and the various possibilities.

The conclusions are that the problem is much more, and almost exclusively, one for the East Bay cities, than for San Francisco, and the desirability of considering the situation from this standpoint very carefully, before definitely fixing on the Hetch Hetchy project, is advised.

INTRODUCTION.

Urban communities on San Francisco Bay in California have proposed to secure additional water supplies. After more than a decade of endeavor, the City of San Francisco, acting in its own name, but latterly in behalf of a metropolitan water district, has just secured permission to use the Hetch Hetchy Valley and dam site on the main Tuolumne River, within the boundaries of the Yosemite National Park. The privilege of doing this was bitterly contested by numerous individuals, societies, and associations. Widespread interest was aroused, and much feeling engendered.

Because of the interesting nature of the problem to the Profession; because of the many engineering facts which have been brought out from time to time in a multitude of reports and hearings before Government officials and Congresses; and because various engineers have differed so widely in regard to many matters, a comprehensive paper on the subject is believed to be timely.

Topography of San Francisco Metropolitan Area.—San Francisco Bay, with its outlet to the ocean—the Golden Gate—is about in the middle of the California coast line.

The relief map, Fig. 1, shows the immediate region. The Northern Peninsula, generally referred to as Marin County, is quite hilly and

AND VICINITY

mountainous, with a relatively small area suitable for urban development. The Southern Peninsula, on which is the City of San Francisco, has a much more favorable, but still unfortunate, topography for city building. The portion south of the corporate line, and as far as the City of Santa Clara, is locally known as the "Peninsula," only the eastern edge of which is level or relatively so. The mainland along the east shore of the Bay from Richmond south has a comparatively narrow strip of level area, changing to rolling, and then to sharply hilly, country. This increases in width toward the south. The total area suitable for urban development on this side of the Bay is many times greater than that in San Francisco and both peninsulas combined.

The range of mountains running along the California coast line—the Coast Range—really ends in Twin Peaks, within the corporate limits of San Francisco, and begins again just across the Golden Gate, extending thence northward.

East of the Bay, another mountain range, parallel to the Coast Range but higher and wider, extends across the entire region, with a very narrow break, known as Carquinez Straits, through which the combined waters of the Sacramento and San Joaquin Rivers are discharged into San Francisco Bay. In many ways this Mt. Diablo Range is a most important topographical feature of the San Francisco Metropolitan District. It modifies in a striking way the local climatic conditions; stands as a barrier against urban growth eastward; affords productive water-sheds and storage facilities for local water developments; and is a very serious obstacle to be overcome in bringing a water supply to the Bay region from those sections of the Sierra Nevada Mountains directly to the east.

Urban Development.—The Mission of San Francisco was established by the Franciscan Fathers on October 9th, 1776, practically in the geographical center of the present City of San Francisco. In 1846 there was only a little settlement, called Yerba Buena, on the shores of Yerba Buena Cove, between Telegraph Hill and Market Street. The name was changed to San Francisco in 1847. With the discovery of gold in California in 1848, the settlement suddenly became important. For a few decades the growth was phenomenal and then dropped to about the normal in cities of its size.

It is unfortunate that the original settlement was not on the mainland, as the available area for satisfactory city development on the Southern Peninsula is relatively small, and is sharply restricted by the topography.

Effect of Topography.—The effect of the local topography has been very marked. The disposition of the land masses affects the fog distribution and results in a peculiarly great variation in climatic conditions over the district. San Francisco's climate is foggy and windy, generally speaking, with summer temperatures only slightly higher than those of winter, the thermometer rarely reaching 80° Fahr., and even a few scattering snowflakes and thin films of ice are to be seen only at intervals of years.*

The city is compactly built, due to the limited area which is not on steep hillsides. As the climate is really quite equable, it is unfortunate that home building was not carried out along the same lines as in Los Angeles and all other California cities, namely, to accentuate and take advantage of the famous climate.

In 1874, the area was materially enlarged by the introduction of cable cars, which were developed to meet the local situation. A railroad built into the interior of the State in September, 1869, naturally ended on the east shore of the Bay, with ferry service into the city proper. The suburban service thus available to the mainland, started settlements in Alameda, Oakland, and Berkeley, where ample space, milder climatic conditions, and cheap individual water supplies resulted in a different type of city building.

At first ocean shipping was of pre-eminent importance, and the development was determined by deep-water wharfage. As railway transportation increased in relative importance, commerce was influenced by the railway terminals on the mainland, but the position of San Francisco as the commercial center has become so firmly established that it is doubtful whether it will ever be transferred across the Bay.

Effect of Geographical Location.—In the nature of the case, San Francisco's population is cosmopolitan and self-sufficient. The city very quickly became a metropolis, and was effectually isolated from any other center. It was the financial and commercial hub of western gold mining enterprise, which attracted the energetic and adven-

* The last snowfall was 1 in., on March 3d, 1896.

turous from all over the world. There are large foreign quarters in other cities of the country, but in San Francisco—except in Chinatown—the many nationalities are diffused. Consequently, its civic, religious, educational, and political ideas and institutions were and are different from those obtaining anywhere else in the United States. It is financially self-made, self-centered, and self-sufficient. The prevailing spirit was, and in large measure is yet, against San Francisco being a "cheap town." It is a wealthy one. Large personal freedom developed, and precedents of all kinds, including engineering methods, quickly came to be regarded lightly—often with excellent results.

In consequence, individualism was developed to an extreme, with a corresponding lack of co-operation. This condition obtains in a less, but still marked, degree to-day.

Considerable manufacturing necessarily developed, and, until the last decade, little was done on the Pacific Coast outside of the city. It became the center of Labor Unionism on the Coast, more particularly after the successful protests of Dennis Kearney and his followers against Asiatic labor competition.

Limits of Greater San Francisco-Oakland, as Used in This Paper.—The census adopts for metropolitan districts all urban population within 10 miles of the municipal boundaries. In this paper, however, the term will be used as including the territory which, logically, should ultimately have a common water supply. It is practically coincident with the region circumscribed by a circle of 30 miles radius with the San Francisco Ferry Building as the center. Greater Los Angeles, similarly, is considered as the area within a radius of 30 miles from the Los Angeles City Hall.

I.—Probable Future Population.

Growth of San Francisco.—For the past three decades the growth of the San Francisco Metropolitan District has been steady, and at the average rate for American cities of like population, but very much slower than Chicago, New York, and several others, when they were of similar size. The disastrous conflagration following the earthquake of April, 1906, temporarily affected San Francisco proper most seriously, but markedly accelerated the development of the East Bay cities and other suburbs. Such effect was not great enough to explain the relatively slow growth of Greater San Francisco-Oakland as com-

pared with all other important centers on the Pacific Coast and in the Far West during recent years.

The reasons for this, and how potent they will be in the future, are questions of primal importance. The population, and consequently the water requirements, are the first things to be determined in planning a water supply.

So far as the writer is aware, those who have estimated the future population of the district have not analyzed the peculiar conditions in California. The phenomenal percentages of increase in Los Angeles, Cal., Vancouver, B. C., Seattle, Wash., and other Pacific Coast cities in recent years, have never been taken into account, except by adding a statement that, remembering them, "the curve may be regarded as extremely conservative." This is not very illuminating.

Growth of California.—In the decade, 1900 to 1910, California's population increased 60.1 per cent. The rate for Oregon was 62.7%, Nevada, 93.4%, Idaho, 101.3%, and Washington, 120.4 per cent. The weighted average for these four other States was 95.9%, and for Washington and Oregon—the two other Pacific Coast States—95.8 per cent. The numerical increase was, Washington, 623 867; Oregon, 259 229; or together, 883 116—only 11 382 less than California.

Relative Growth of Northern and Southern California.—On examining detailed figures, it is found that the excessive population increase of the State is not of California generally, but of Southern California, consisting of the seven counties south of the Tehachapi—Ventura, Los Angeles, San Bernardino, Orange, Riverside, San Diego, and Imperial. The growth of population in these seven counties was 154%; in the rest of the State it was only 38%, and in the census San Francisco Metropolitan District but 41 per cent. The curves, Figs. 2 to 10, indicate that, unless something in the nature of widespread calamity or war occurs to change the respective rates of growth, Southern California will, by 1920, comprise more than half the State in all essential respects except area.

There are several reasons why this is surprising. They must in time be effective. These, in the probable order of importance, are:

1.—The natural resources of the State, like its precipitation, increase approximately in direct ratio from south to north. A marked

exception, whereby the reverse is true, is the attractiveness of the ocean beaches.

2.—The climatic conditions of Southern California, from a residence point of view, are inferior to those of the central and northern parts. This fact has been obscured by the effective advertising of Southern California. Greater San Francisco-Oakland is climatically

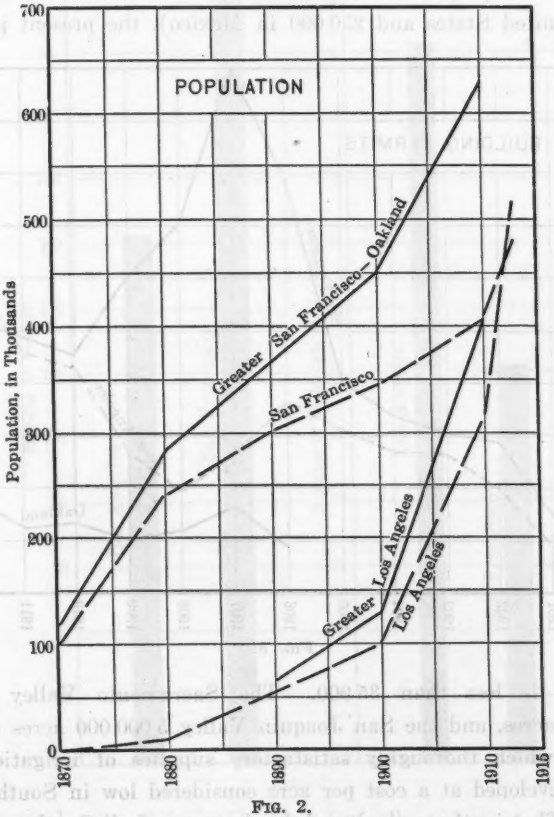

FIG. 2.

a markedly better summer resort than Los Angeles, and probably is not equalled anywhere in America.

3.—Within easy reach of San Francisco lies some of the most picturesque scenery in the world. There are opportunities to construct about the Bay cities the most attractive and beautiful roads

and boulevards on the Continent, and the Bay is almost unrivaled for yachting and motor boating the year round.

4.—The agricultural and horticultural possibilities of Southern California are literally dwarfed by those of the Central Valley—Sacramento and San Joaquin Valleys—alone. The total irrigated area of Southern California is a little more than 300 000 acres, exclusive of Imperial Valley (which will ultimately contain about 500 000 acres in the United States and 250 000 in Mexico), the present population

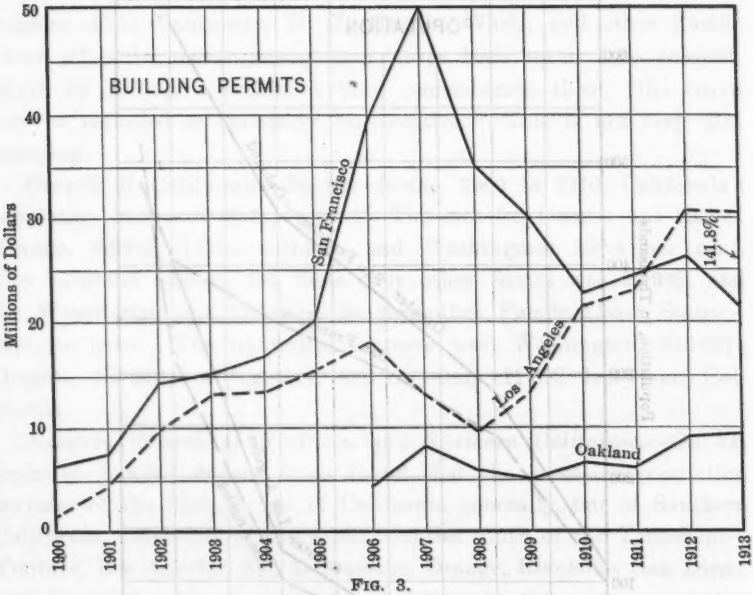

FIG. 3.

of which is less than 35 000. The Sacramento Valley contains 2 250 000 acres, and the San Joaquin Valley 5 000 000 acres of fertile land for which thoroughly satisfactory supplies of irrigation water may be developed at a cost per acre considered low in Southern California. That is, the agricultural development of all Southern California, which was the foundation for its entire development, is only 4% of the easily irrigable area of the Central Valley alone. Furthermore, the proportion of irrigable area adapted to growing oranges, lemons, grape-fruit, etc., is about the same in each region. When it is remembered that California produces 40% of the world's commerci-

ally grown oranges, and that the groves scattered about the Sacramento and San Joaquin Valleys have shown that oranges ripen there at least 6 weeks earlier than in Southern California, and suffer less from frosts, some realization of the situation can be obtained.

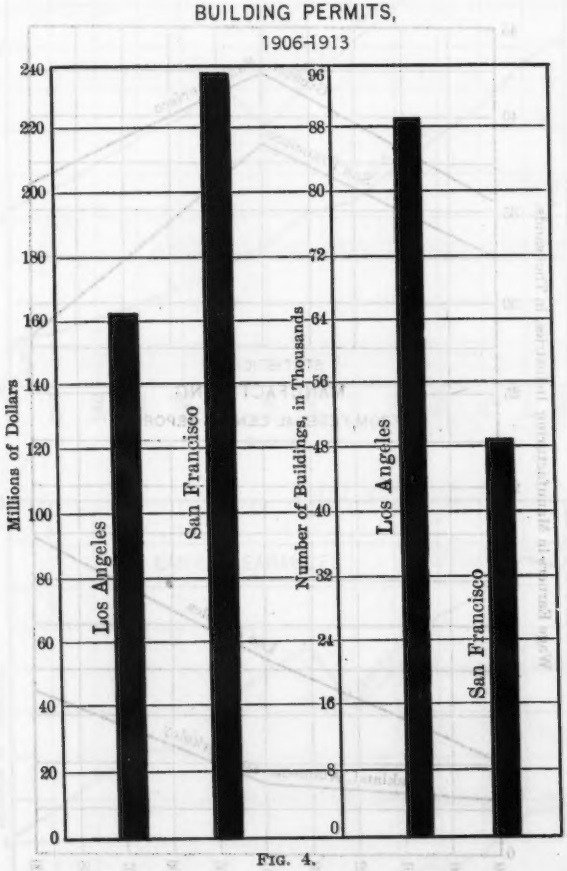

FIG. 4.

The total area of irrigable land logically tributary to San Francisco is 12 500 000 acres, and that of arable land is 15 393 000 acres.

5.—Thirty years ago, when Los Angeles had only 12 000 inhabitants—mostly Mexicans—San Francisco had 250 000, and was the "City" to which people "went down" from a vast region extending nearly 1 000 miles south, east, and north; it was practically the only

seaport on the Pacific Coast, and for more than 10 years was the western terminus of the only transcontinental railway.

In other words, the soil of Southern California is, to say the least, no more fertile; the water supply is by comparison pitifully

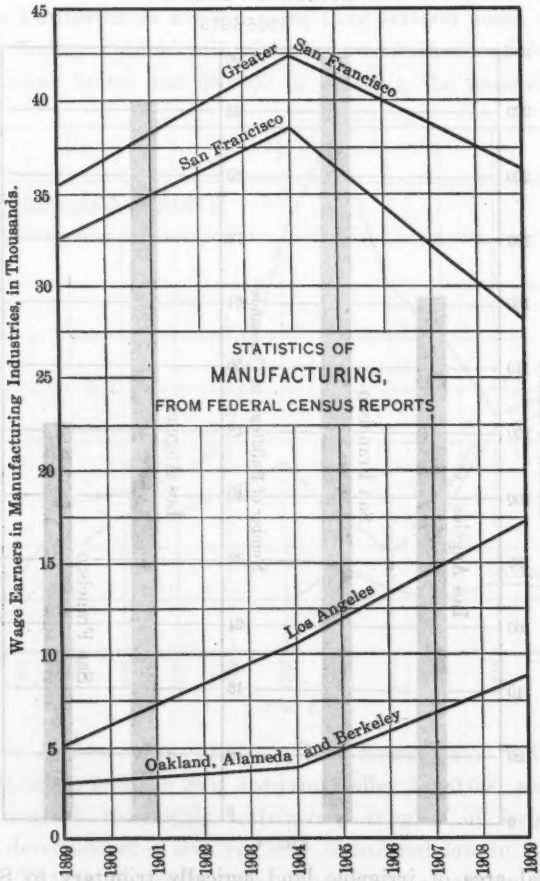

FIG. 5.

deficient; the climate not so delightful nor perfectly adapted to fruit culture, especially oranges and lemons; the extent of back country which can ever be made suitable for intensive farming, but a small fraction of that logically tributary to San Francisco; the natural

harbor and the shipping facilities hopelessly inferior; and the southern country so far behind in population 30 years ago that no one dreamed of real competition.

Under such conditions why should Los Angeles to-day have more inhabitants than San Francisco, with 86% as great an assessed valu-

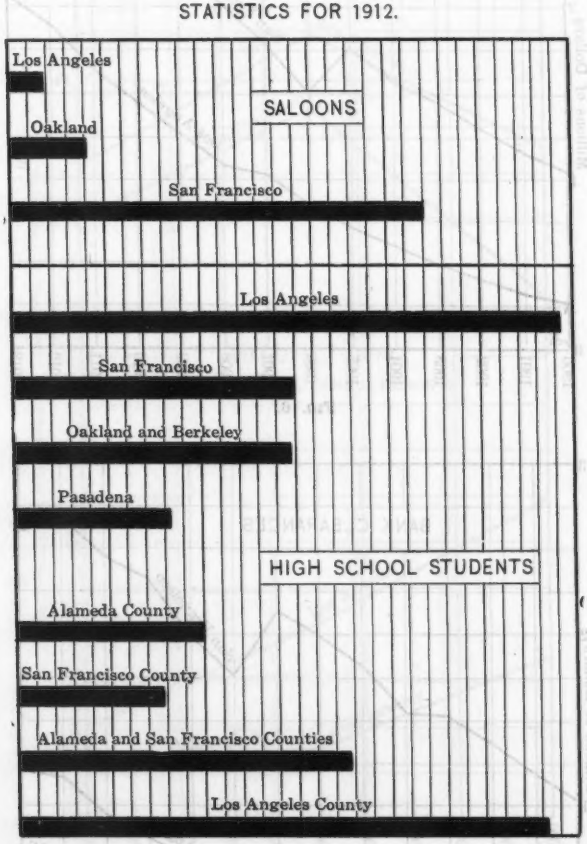

FIG. 8.

ation, and Greater Los Angeles nearly as many people as Greater San Francisco-Oakland, with a similar assessment ratio, and still growing tremendously faster than the northern center?

It seems to be a case of the hare and the tortoise. Natural advantages in the Sacramento and Upper San Joaquin Valleys resulted

in great bonanza grain farms—one man having raised on his own land holdings in a single season 1 000 000 bushels of wheat. It is an economic crime to devote such land, with its extraordinary crop adaptation and wonderful climate, to grain culture. In the Southland scanty rainfall compelled irrigation, and irrigation and citrus

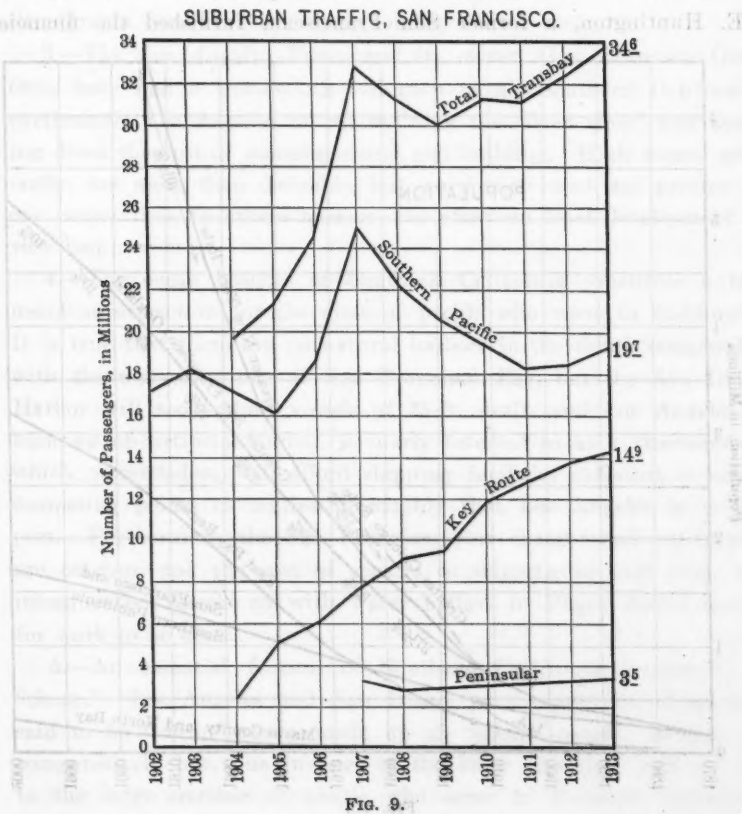

FIG. 9.

culture have been more highly developed there than anywhere else in the entire world.

However, the tremendous advantages of irrigation in the State were fully demonstrated 40 years ago, so that, in addition to this fundamental reason, there must be others quite as potent. These, in the probable order of importance, are:

1.—The Los Angeles Chamber of Commerce. This is doubtless the most efficient organization of its kind in the world, presenting a united, brave front in all matters affecting the development of, not only Los Angeles, but all Southern California. It is doubtless unequalled as an effective advertiser.

2.—The Pacific Electric Interurban System, for which Mr. H. E. Huntington, a former San Franciscan, furnished the financial

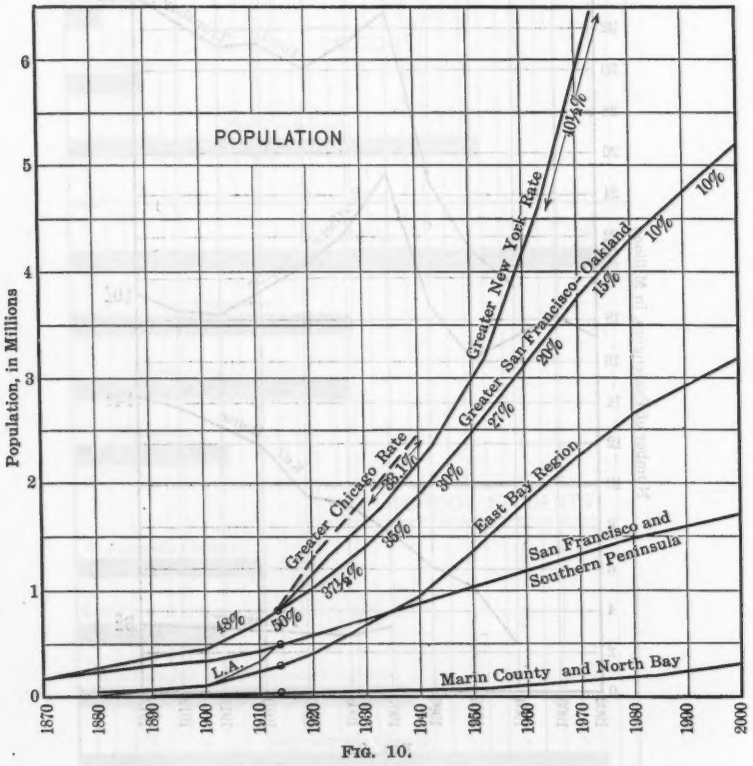

FIG. 10.

strength, and Mr. Epes Randolph, now of Tucson, Ariz., outlined the broad general plans. It is the most complete, extensive, well-constructed, and well-equipped system of interurban electric railroads in the world. There are 6 200 daily train movements over 47 routes, the total number of passengers carried yearly being more than 106 000 000. The total annual trans-bay suburban traffic between San

Francisco and Oakland, Berkeley, etc., is less than 35 000 000, or about one-third, in spite of the fact that such suburban service is, next to that of Los Angeles, the best and cheapest on the Continent.

In addition, there is doubtless no city in the United States—and that means the world—with a system of surface electric roads as modern and well-equipped as Los Angeles. The street railway situation in San Francisco is deplorable.

3.—The *Los Angeles Times* and its owner, Gen. Harrison Gray Otis, have had a tremendous influence in all Southern California, particularly Los Angeles, in maintaining the "open shop" and keeping down the cost of manufacturing and building. High wages, generally, are more than desirable, but when shop costs are greater in one center than in others near-by, the effect on local development is very bad.

4.—The ocean beaches of Southern California constitute a tremendous attraction for the class of people who come to California. It is true that there are no natural harbors in the South comparable with the marvelous one of San Francisco Bay, but the San Diego Harbor will soon admit vessels of 35-ft. draft, and Los Angeles is building an artificial harbor, jocularly referred to as a "harborette," which, nevertheless, will afford shipping facilities sufficient to cause competing points to realize thoroughly that Los Angeles is a seaport. Furthermore, the San Francisco port charges and regulations are onerous, and the cost of repairs to shipping so high that, not infrequently, vessels go with water ballast to Puget Sound points for work to be done.

5.—An essential feature of Southern California is that it is "cheap." Los Angeles and San Diego, particularly, are frequently said to be "cheap" towns made up of "cheap" people. Wages are comparatively low, due in part to the labor situation, and in part to the large number of people who come to Southern California determined to remain. All the larger places are surrounded by country topographically suited to indefinite urban expansion in all directions. Consequently, labor and rents are cheap. The expression "Southern Cafeteria," used derisively, has played a very important part.

6.—The fact that Southern Californians are often sneeringly referred to as "goo-goos" (goody-goody) has been an effective adver-

tisement. San Francisco, on the other hand, has been widely advertised as the "Paris of America." There are 200 saloons in Los Angeles and 2 200 in San Francisco proper, and Los Angeles has more than twice as many high school students.

7.—Until a decade ago, San Francisco was, politically, the State of California, and was practically governed by railway interests. Of all boss-ridden commonwealths in the United States, California took first rank, and bribery, "influence," and manipulation of public affairs for the Interests controlling the machine became accepted as a matter of course. The moral fiber of the community was seriously affected. The influx into San Francisco was relatively small, but the tremendous increase in the population of Los Angeles came from all over the United States, bringing a strong strain of Puritanism and higher civic standards. The result for Los Angeles is a community which can and does co-operate and trust its leaders, and secures vastly more advanced civic improvements, of which the water supply is the most striking.

The years of wrangling about San Francisco's water supply and private ownership of the present water system are not accidents, they are only some of the costs of its individualistic temperament.

8.—Because the newcomers quickly outnumbered the natives, Southern California is really not "Western" at all, but a sort of general average of the entire United States and Canada—particularly east of the Rocky Mountains—in education, political and religious ideals, institutions, and spirit. The large cost of railway transportation from New York to the Coast has kept the percentage of European immigration very low. The influx into the State naturally goes to that portion having the same civilization and ideals as the newcomers. Consequently, almost everybody in America has acquaintances, friends, or relatives in Southern California—often very many of them. The result is an "endless chain" never elsewhere equalled.

9.—This factor has been intensified by the limited areas available for intensive cultivation. No large irrigation or colonization schemes were there desirable or even possible. Small, entirely distinct and independent tracts were often settled almost wholly by people from one general community. For example, the Ontario Project, promoted in 1888 and carried to a successful conclusion by

Messrs. William and George Chaffey, formerly of Ontario, Canada, was largely settled by Canadians from that Province, and hence the name. The various settlements—Riverside, Redlands, San Bernardino, Ontario, Pomona, etc.—have retained their individuality. All newcomers have been pouring into small tracts having a gross area of about 300 000 acres, so that the real population density of the inhabited portions of the region is fairly high. The communities have been well established since 1895, and with practically no pioneering work since 1900. So far as municipalities are concerned, however, the reverse is true, in that there are unlimited areas available for urban growth in every direction.

10.—Due to the progressive spirit, the high average and extremely well distributed wealth, and the fact that the country is a tourist playground, automobiling in Southern California is more general than in any part of the world. This quickly resulted in the construction throughout almost the entire region of a system of beautiful boulevards. These have gone far to eliminate what little "pioneering" work was left to be done there a few years ago.

11.—All the scenic attractions of the Southland have been made easy and comfortable of access and brought emphatically to the attention of every tourist. Although the San Francisco Bay region naturally offers much more in every way except ocean bathing, and might be made one of California's greatest scenic assets, this certainly has not yet been done. Thus, Southern California has come to be regarded as the nation's playground and residence section *de luxe*, where the tourist spends his weeks and months while his visit to San Francisco is ordinarily of but a few days *en route*. For this reason it is extremely probable that the Panama-Pacific Exposition in San Francisco in 1915 will really benefit Southern California much more than the Bay region, especially as another peculiarly unique and attractive, though less expensive, Exposition will be held simultaneously in San Diego.

12.—California is in an earthquake region in the sense that *tremblors* are not infrequent. The damage from the shocks of April 18th, 1906, in the East Bay cities was insignificant. In San Francisco proper the chief damage was the breaking of the gas and water pipes in the filled-in areas, thus interrupting the main water supply. This caused one of the disastrous fires of history.

Property worth $350 000 000 was wiped out of existence, many of the inhabitants were widely scattered, and the normal development of the city was violently interrupted. Los Angeles, and to a much less degree, other Coast cities, gained thereby. The final effect on the size of the two cities, however, has been much less than is generally supposed. San Franciscans have nearly all returned. The financial status of many individuals was greatly altered, and the city as a whole is less wealthy than it would have been. Otherwise it, and particularly Greater San Francisco-Oakland, was benefited in many important ways. The effect of the disaster on the location of newcomers to the State was very marked for a time, and doubtless is still appreciable. However, even a great disaster rapidly fades from the world's memory. Los Angeles, quite as much as San Francisco, is in the *tremblor* district, and has fully as many tremors, and by the law of averages the northern city is the safer. Nowhere in the State has a really severe earthquake occurred in historic times; disastrous shocks are like lightning, in that they may strike anywhere. These facts are now generally understood and realized.

Class of Domestic Immigrants.—The people who come to California have not the slightest intention of pioneering, but rather of obtaining the pleasantest home within their means. This is a fundamental fact. That agricultural and suburban land values are from two to five times higher in Southern California than in the Northern sections has not yet had any marked effect, although, of course, it must in time.

It is of the greatest importance to realize that, 20 years ago, when the growth of Southern California began to be really phenomenal—not so much in percentage of population increase as in actual amount and character—the region was agriculturally and horticulturally quite fully developed. There were thrifty, well-matured groves and orchards covering more than two-thirds of the area now devoted to horticulture, with practically all the present steam railway mileage in operation, and beach, park, driveway, and scenic resort development done. In short, all "pioneering" was a thing of the past.

It was then that the future began to be discounted, boosting became general, the Pacific Electric System was built, the oil fields were exploited, and extraordinary growth commenced.

Probable Future Growth Within the State and of Greater San Francisco-Oakland.—To what extent and how quickly may these influences and conditions be expected to change, and with what results?

San Francisco is a big city, and its characteristics will change but slowly. Nevertheless, recently there have been some important forces in addition to those generally in operation. From within there are such people as the Rev. Dr. Aked, Bishops Hughes and Nichols, Jack London, Charles Tenney Jackson, Miriam Michelson, and a number of others, and the great University of California, which has the largest body of undergraduate students in America and strong graduate departments. Those parts of Greater San Francisco-Oakland having less of the Argonaut characteristics are rapidly gaining, and within a couple of decades will outnumber and constantly more deeply influence the main city. From without, the majority vote which the remainder of the State brings to San Francisco has forced woman suffrage, suppression of race-track gambling, throwing off railway political domination, etc. A red-light abatement act would have become a State law a few months ago had not a referendum petition held it up until the November, 1914, election, and San Francisco has already abolished its notorious Barbary Coast. By the initiative, next fall, California will vote on State-wide prohibition.

Thus Greater San Francisco-Oakland is quite rapidly reducing the advantages which Los Angeles urges so strongly, of a "wholesome atmosphere" for family life, although probably two or three decades will be required to secure any degree of parity in this regard between the two great centers.

It will doubtless be a decade before the Chambers of Commerce and Development Boards in Greater San Francisco-Oakland and Central California will speed up to the present Los Angeles standard. It will be at least as long before the present unsatisfactorily financed beginnings of an electric interurban system develop to the Pacific Electric standard, and longer before the natural attractions of the Bay region are fully utilized. The cost of living will probably always be lower in the Southland, and the beach advantages will never be offset, although the counter attractions of the northern Sierra Nevada Mountains will be made more and more important.

With rapidly increasing Far Eastern trade, the great San Fran-

cisco Bay must become an increasingly important factor. The route to the Orient from Puget Sound is more foggy and less safe, and from San Diego and Los Angeles, longer. San Francisco is the logical commercial center—the New York—of the Pacific Coast.

The Panama Canal will have an important effect, but for quite a few years much less than many seem to think. For a number of years other Coast cities will probably benefit almost as much as, if not more than, the Bay cities, particularly with lower manufacturing, handling, and ship repairing costs, due to lower wages and rents.

Within the last 4 or 5 years enormous areas in the great Central Valley have been thoroughly developed, from a land-and-water-company point of view, for sale in small tracts to home builders. The grand total is much more than 1 000 000 acres, equal or superior to, in every regard—except environment and convenience—and held at from one-half to one-fourth the prices of, lands with similar crop adaptation in Southern California. Unfortunately, the general idea has not been to use the land, but to build irrigation works and "colonize." Conditions have changed in the two or three decades since the Southland was developed. In 1880, 70% of the people in the United States were on the soil, to-day but 51 per cent. Subduing and farming irrigated lands is by no means a poor man's business, and in general those who have enough capital to succeed will not pioneer.

Already the large companies see the "handwriting on the wall" and are arranging to prepare, plant, and cultivate the land—develop it completely, and then sell farms and orchards, rather than raw land and agricultural and horticultural problems to individuals. A noteworthy instance is the Mills Orchard Company, which is planting about 10 000 acres of orchards, mostly lemons, at about the midpoint on the west side of the Sacramento Valley.

The State is putting $18 000 000 into a network of permanent highways, and the good roads movement is in full swing in the Central Valley.

Several careful students of conditions in California believe that the State is likely to have a single-tax law within the next decade, especially as the initiative is available. In this event the effect on the lands in question would be tremendous.

Taking all these things into consideration, it would seem that,

in about a decade, the great Central Valley will reach the point where Southern California was 20 years ago, and will develop thereafter in much the same way as the Southland is doing. Also, on account of the increasing tendency to concentrate in large cities, the effect on Greater San Francisco-Oakland will be much the same as the development of the southern country has been on Los Angeles. This in spite of the great extent of back country and the consequent development of relatively large local centers such as Sacramento.

Manufacturing on the Pacific Coast must also increase, but whether faster or slower than the agricultural and horticultural interests depends on several factors. Northern and Central California, Washington, and Oregon, particularly, can and will have more and cheaper hydro-electric power than any other place in the United States, and the rates and service will be, and already are, completely controlled and regulated by utility commissions. California has enormous quantities of fuel oil, but its cost is now equivalent to coal at about $4 per ton, and there is little probability of material reduction. The climatic conditions of San Francisco conduce to the highest labor efficiency on the Continent. The local market is important and rapidly increasing. The Panama Canal will make cheaply accessible enormously greater territory. San Francisco is the nearest point in the United States to the potentially tremendous consuming countries in the Far East.

The present high wage rates and unsatisfactory local labor situation make it unwise to expect very great increase in the near future. Nevertheless, it seems probable that the wage "differential" in favor of the other Far West cities will gradually be eliminated, especially in view of the general tendency toward State and National arbitration of labor disputes, laborers' compensation laws, etc.

It is impossible, of course, to evaluate numerically these many factors, but such is always the case in projecting population curves. Regarding Greater San Francisco-Oakland, it would appear that:

1.—There is no probability of excessive rates of growth for the next 10 or 15 years.

2.—The increase for 1910-1920 will be considerably greater than that for 1900-1910, during which the great fire occurred.

3.—The increase after about 1925 will be very rapid for several decades.

Probable Growth of Various Parts of Greater San Francisco-Oakland.—Of almost equal importance for the matter at hand is the division of the total growth between the main, east-bay, and suburban centers.

The influences resulting in the various local growths have been set forth, chief of which is available area. San Francisco has a population density of more than 10 000 per gross sq. mile, and probably 15 000 per net sq. mile. In Marin County, the area available for city development within a reasonable time zone is relatively small and scattered, so that the suburban traffic facilities are, and, for some time, will probably continue to be, below the other local standards. Nevertheless, the climatic conditions are peculiarly attractive and the region so picturesque as to assure great suburban development of a high grade, with excellent transportation service. The population down the Peninsula will be much denser, but always essentially suburban to San Francisco alone. At the south end of the Bay is San José, as old as San Francisco, about 45 miles from it and from Oakland. It is now, and doubtless for several decades will be, a local center rather than a suburb.

The trans-bay cities, Oakland, Alameda, Berkeley, etc., which are physically one city, were the result of San Francisco's natural barriers, in spite of a suburban trip so onerous as to begin to alienate them when well grown. Another vital factor is the mainland transcontinental, and the most important of the local railway terminals and shops. Fig. 9 shows the trans-bay traffic. After the disaster in April, 1906, very large numbers of San Franciscans went to suburban points for temporary shelter, and gradually came back home in 1908. Since then this factor has been unimportant.

Although the East Bay cities are growing at rates somewhat like that of Southern California, and very much faster than the main city, they are also developing a greater independence and self-sufficiency. The social and political conditions existing in these communities are essentially different from those in the main city.

A bridge from San Francisco to the mainland has often been suggested, in fact a bill is now before Congress authorizing one. The trans-bay traffic indicates that such a structure, or a "tube"—which would be much more expensive—is not economically justified, and probably will not be for a long time.

The curves, Fig. 10, show the writer's conclusions from consideration of a great number of elements, chief of which, however, are those just given. All urban population estimates for a period of more than one-third of a century have a sharply limited value. Revolutionary changes, due to inventions, different ideals and tastes—such as a real "back-to-the-soil" movement would typify—cannot be anticipated.

II.—Probable Water Consumption.

Average Daily Consumption Per Capita.—The per capita consumption of water seems to be constantly increasing in all great cities of the United States, and at a somewhat slower rate in most European cities, largely due to higher standards of living. When meters are installed, large water wastes stop, causing an immediate drop in consumption, but an increase at once begins. There is no reason why liberal use should not be encouraged. This necessity and luxury of modern life costs less than any other, when compared with the real comfort it affords. At any rate, the increased consumption in American cities has greatly exceeded the expectations of 20 years ago.

San Francisco has a relatively low per capita consumption, which, in spite of the cool summers, warm winters, and foggy climate, can hardly continue. Wages are high, and people spend freely for comforts. Outside San Francisco proper there will be a marked increase in the use of water for lawns and gardens.

John R. Freeman,* M. Am. Soc. C. E., concludes that the use in Greater San Francisco 50 years hence will be "125 to 150 gallons per capita per day, although by that time substantially every service is metered." The probable curves for all component parts and for the entire Metropolitan District are given in Fig. 11. If anything, the quantity for San Francisco proper is higher in comparison than for the other parts of the district.

Probable Gross Requirements of Greater San Francisco-Oakland and Its Component Areas.—Ordinarily, combining the population and daily per capita consumption curves gives the gross water requirement, but, in semi-humid and arid territories, this is not quite the case. In this district a considerable area is devoted to agricultural purposes, not a little of which will be used in this way,

* "The Hetch Hetchy Water Supply for San Francisco, 1912;" Report by John R. Freeman, San Francisco, July 15th, 1912, p. 79.

even when the population of the district reaches 5 000 000. Until required for city uses, these lands will be cultivated more and more intensively with consequently greater reliance on artificial and controlled watering.

The underground resources made available by wells and the local surface run-off naturally tributary to the region and which can be conserved at a reasonable cost, would be considerably more than sufficient for the arable land. However, much of such water is used in the main and East Bay cities, and it is impossible in considering the water situation of the district to separate the two kinds

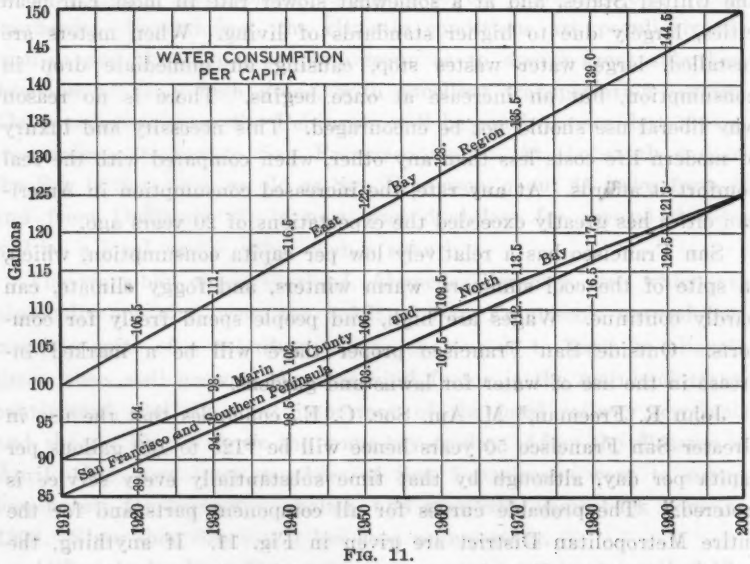

FIG. 11.

of requirements. Consequently, the easy and apparently direct way is ordinarily to obtain the gross water requirement by combining the urban and irrigation uses. Subtracting from these the quantity which may be secured locally, gives the quantity to be brought from a distance.

In doing this, however, it must be borne in mind that well water now available for irrigation and quite satisfactory in quality for domestic purposes will become unsatisfactory for the latter use without effective purification, when the region becomes urban in char-

acter. Hence, it is not correct to assume that the duty of water in residential city areas is, as in Southern California, the same as for horticulture and intensive farming.* Wherever irrigation water is drawn exclusively from very deep water-bearing strata, such fortunate balance may exist, but most of the irrigation water in the district and a great deal of the present East Bay city supply comes from shallow wells.

At present probably 50 000 000 gal. daily, or about 55 000 acre-ft. per annum, are used for irrigation within the district. By the time Greater San Francisco-Oakland has 4 000 000 people, this may be doubled for the area then cultivated, which could hardly exceed from 75 000 to 80 000 acres with croppings requiring about 1½ acre-ft. gross, per annum, in dryer years. Of this acreage, at least one-third would probably be watered from wells, and the remainder of the supply, say, 67 000 000 gal. daily, would be taken from the municipal water district system.† On this assumption the curves on Fig. 12 are drawn.

The grand total consumption curves are derived by adding the supplies for urban and agricultural uses.

III.—Existing Water-Supply Systems.

There are 50 water systems in Greater San Francisco; 20 in the South Peninsula, of which 8 are municipally owned; 12 in the East Bay Region, 4 being municipally owned; and 20 in the North Peninsula and Coast, of which 2 are publicly owned.

San Francisco Proper and South Peninsula.—On the South Peninsula, all but two are relatively unimportant: The municipal high-pressure fire system and the privately owned Spring Valley Water Company of San Francisco. The fire system, completed in 1913 at a cost of $5 200 000, is said to be the most modern and efficient ever built, and protects 8.25 sq. miles.‡ Special precautions were taken to make it as nearly earthquake-proof as possible. Salt water is used only in emergencies and by the two fire-boats on the water-front.

The Spring Valley Water Company has the largest privately owned system of its kind in the world. Fortunately, from a construc-

* This was first pointed out by William Mulholland, M. Am. Soc. C. E., in connection with the estimated water requirement of the City of Los Angeles, when the Los Angeles Aqueduct was under consideration. Practically none of the territory marked out for the future development of Los Angeles secured irrigation water from shallow wells.

† C. D. Marx, M. Am. Soc. C. E., adopts 95 000 000 gal. daily for a much greater district, including a considerable part of Santa Clara County.

‡ The City and County of San Francisco have a total land area of 47 sq. miles.

tion point of view, all planning and building for a period of 43 years ending in 1911, were under one man, Hermann F. A. Schussler, M. Am. Soc. C. E. It was his rule to project his work in considerable detail for 10 years, and, true to his German technical training, he was never satisfied with "good enough work."

Distribution systems in all cities are piecemeal growths. Present conditions, such as sky-scraper construction, were not foreseen. In general, considerably different plants would be installed to-day. Due to the relief afforded by the municipal high-pressure fire system, the high class of construction, and the consistent policy of Mr. Schussler, the distribution system in San Francisco is doubtless the best, with the possible exception of Omaha, Nebr., of any important city in America, so far as it goes. Because of litigation over rates, begun in 1903, very little extension into newer districts has been made. The estimated cost of all desirable work, including extensions, up to 1920 is $2 500 000.

The company collects water from adjoining mountainous areas on both sides of the Bay, as shown in Fig. 1, and distributes 95% thereof in San Francisco proper. The quality is excellent, better than that of any city of half its size in the United States, except as to hardness. This is now about the same as the water of Washington, Chicago, Cleveland, and Louisville, and less than the Owens River supply, to be brought in by the Los Angeles Aqueduct. It will become less as the proportion obtained from surface sources increases. It will be difficult for engineers of the East and Middle West to believe that all present surface supplies come from watersheds having but 18 inhabitants exclusive of employees of the company. The company has carried water-shed protection farther than has ever been even considered east of the Rockies, purchasing outright more than 100 000 acres of water-shed land.

The present daily consumption on the South Peninsula is about as follows:

San Francisco:*	
Spring Valley Company	40 000 000 gal.
San Mateo County	16 000 000 "
Part of Santa Clara County	10 000 000 "
	66 000 000 gal.

* In addition wells and Bay supplies are used in manufacturing, to an unknown extent.

East Bay Region.—On the mainland, the important factor is the Peoples Water Company, which supplies practically all the water used in Oakland, Alameda, Berkeley, and several smaller places. Unlike the Spring Valley Water Company, it is the successor of nine lesser companies which entered the field during the past 45 years. These companies, becoming unable to meet the rapidly increasing demand, were successively displaced by stronger ones. According to J. H. Dockweiler, M. Am. Soc. C. E., who has been Consulting Engineer for the Cities of Oakland and Berkeley for a number of years, the history of these attempts to keep pace with the widely scattered and rapidly growing population centers by private capital is a most interesting and curious succession of failures properly to grasp opportunities and protect investments by adequate preparation for the future. According to him, largely as a result of 5 years' relentless and wasteful competition between two such companies, the distribution properties are in a considerable degree superimposed on each other; short-lived materials have been used extensively, and the mains and reservoirs are out of consistent relationship with the topography of the territory and the developed sources of supply. According to his records, 48% of the nearly 900 miles of pipe are 2-in. and less, and only about 30% are of cast iron. The area served is 67 sq. miles, 27 of which are above the 200-ft. contour, and it is divided into sixteen pressure zones or areas, ranging from sea level to 1 000 ft. elevation. The system has 60 000 connections, 95% of which are metered, relatively few fire hydrants, and average receipts of 25 cents per 1 000 gal., with base rates as high as 35 cents.

About 100 blocks of the business section of Oakland are covered by a municipal fire system costing, to date, $136 000. Elsewhere on the mainland the fire protection is, in general, very poor, and in many areas negligible. The situation in this regard is probably as unfortunate as in any important center in America.

About one-third the water comes from the surface supplies of the company, shown in Fig. 1, and almost all the remainder from wells near the Bay shore. According to Mr. Dockweiler, the quality is generally satisfactory, although hardly up to the standard of that supplied to San Francisco. The present daily consumption is:

Peoples Water Company:	
Surface	7 000 000 gal.
Underground	11 000 000 "
Union Water Company	700 000 "
Other systems	3 000 000 "
Private wells, about 4 000	8 000 000 "
	29 700 000 gal.

This is exclusive of irrigation water.

Marin County and North Bay Region.—The four principal systems are the Marin Water and Power Company, the North Coast Water Company, the Vallejo Municipal Water-Works, and the Benicia Water Company, the latter being privately owned. The first two are supplying about 2 000 000 gal. daily from surface sources, and the others furnish water for Vallejo (population, 15 000) and Benicia (population, 3 000).

IV.—Maximum Safe Yields of Existing Sources.

The maximum safe yields obtainable by the complete economical exploitation of the various local developed and undeveloped sources are about as follows:

San Francisco and Peninsula.—The complete development of the Spring Valley Water Company's sources of supply would require creating the Calaveras Reservoir, by building a dam 220 ft. high, work on which is now in progress; two other reservoirs, San Antonio and Arroyo Valle, all in the Alameda Creek water-shed; and the diversion of other Coast streams into the Peninsula reservoir system.

The Calaveras Reservoir, estimated cost, $1 500 000, will have a capacity of 53 000 000 000 gal., or 162 700 acre-ft. The flow-line elevation will be 790 ft., and the contributory water-shed is 100 sq. miles, or with the Upper Alameda water-shed, 140 sq. miles.

The San Antonio Reservoir, estimated cost, about $750 000, will have a capacity of 11 500 000 000 gal., or 35 300 acre-ft. The flow-line elevation will be 455 ft., and the contributory water-shed, 38.7 sq. miles.

The Arroyo Valle Reservoir, partly storage and partly regulating, is estimated to cost about $800 000, and to have a capacity of 13 000 000 000 gal., or 39 900 acre-ft. Its flow-line elevation will be 800 ft., and the

contributory water-shed, 140 sq. miles. It is estimated that the related development of underground sources in Pleasanton Valley and at Sunol will cost $1 300 000.

The Peninsula development will intercept the run-off from 65 sq. miles of territory, contributory to Pescadero and San Gregorio creeks, and convey it by canals, pumps, and tunnels into the Crystal Springs Reservoir, at an estimated cost of $8 500 000 for 50 000 000 gal. daily, or $170 000 per 1 000 000 gal. daily.

The maximum yield which could thus be economically secured for use in San Francisco proper has lately been the source of much bitter controversy. Since 1910 an extraordinary number of engineers, usually believed to be especially competent in such matters, have made examinations and have reported widely differing results, as indicated in Table 1.

There are complete records of gauge heights and draft on reservoirs as follows:

Crystal Springs .....1888 to date.
San Andreas .....1870 " "
Pilarcitos (Except totals only for 1889 and 1898-1902) .....1867 " "
Lake Merced (With several breaks prior to 1906) .....1883 " "

There are run-off and discharge records as follows:

Niles Dam .....1888 to 1900.
Sunol Dam .....1900 to date.

* Pilarcitos, San Andreas, and Crystal Springs. † Including Lake Merced. ‡ 25 000 000 000 gal. storage. § Includes Coast streams connected with enlarged (Lower) Crystal Springs Reservoir and also surplus from Calaveras, but does not include San Antonio, Arroyo Valle, Pleasanton, or Sunol gravels.

The territory from Greater San Francisco's southern limits on both sides of the Bay to the south end of the Santa Clara Valley can be fully supplied from the remaining local surface and underground water sources within reasonable limits of cost. There will be little excess, however.

East Bay Region.—The maximum safe yield of underground sources is problematical; it depends primarily on the extent to which the various fruitful underlying water strata are supplied from local sources, such as delta fans and cones, and from distant exposed Pleistocene gravels. Considerable difference of opinion exists regarding this matter, also. Definite conclusions are not yet justifiable as to the extent to which the present draft of probably 12 000 000 or 13 000 000 gal. daily may be safely maintained or increased.

The Peoples Water Company proposes to increase the local surface water supplies by building three dams on San Pablo, Upper San Leandro, and Pinole Creeks, thus creating three collecting and storage reservoirs.

The first of these it is estimated will cost about $2 335 000, have a capacity of 6 000 000 000 gal., or 18 420 acre-ft., and a flow-line elevation of 325 ft. The water-shed is 34.65 sq. miles and the estimated safe yield 8 000 000 gal. per day.

The second reservoir, on San Leandro Creek, estimated cost $2 878 000, would have a capacity of 16 700 000 000 gal., or 51 270 acre-ft., and a flow line at an elevation of 470 ft. The water-shed is 32.94 sq. miles. Below it is the present Lake Chabot or San Leandro Reservoir from which more water is wasted than impounded in seasons of average precipitation. The upper reservoir would conserve all the run-off, and thus increase the safe daily draft about 10 000 000 gal.

The third, on Pinole Creek, the last which would be created, would cost about $676 000, have a capacity of 2 300 000 000 gal., or 7 060 acre-ft., and a flow line at an elevation of 290 ft. The water-shed is 10.5 sq. miles, and the safe draft would be about 3 000 000 gal. daily.

These proposed reservoirs are practically contiguous to built-up areas. In time their water-sheds will be built on, at least, it is desirable that the area be available for the rapid growth of population. It would be necessary to filter the water carefully. The utilization of the San Pablo and Pinole sites would affect the annual water replen-

ishment in the delta cones of these creeks where a considerable number of wells are in use. The quantity of water required to be delivered to such regions as recompense, would be about 1 500 000 gal. daily.

The Richmond Water District plans are for a distant supply from the Sacramento River.

Marin County and North Bay Region.—The plans outlined by the Marin Municipal Water District provide for a total safe draft from local sources of 14 000 000 gal. daily, which is regarded as the maximum feasible limit. In the North Bay region the available increase from local water sources is relatively insignificant.

Summary.—The total ultimate safe draft for municipal purposes, of a quality quite satisfactory and well above the present standards for important cities in America, and obtainable at a reasonable cost by complete development of local sources is, then, about as follows:

For San Francisco and Peninsula.....	180 to 200
" East Bay Region.....	37 to 40
" Marin County and North Bay Region....	14 to 16
	231 to 256

V.—CAN GREATER SAN FRANCISCO-OAKLAND AFFORD A SIERRA SUPPLY?

San Francisco proper has available a disproportionately large part of the local water yield. By complete development, which can be done piecemeal as necessary, it can have an ample supply of excellent quality for at least 75 years to come, exceptionally large local reservoir capacity, and consequently relatively small upkeep and danger of interruption from floods, landslides, or earthquakes.

The city's present assessed valuation is $623 000 000. To acquire the Water Company's properties needed will cost between $35 000 000 and $40 000 000. The city has not finished rebuilding following a $350 000 000 fire. It has a total authorized bond issue of $43 000 000, exclusive of the Hetch Hetchy issue of $45 000 000 which latter is authorized, but not put out. Because of an exceedingly bad transportation situation, it is well started on a programme of taking over and operating all traction lines within its limits. This will require an estimated expenditure of between $100 000 000 and $125 000 000 during the next 25 years. It has no elevated or subway systems, though these are needed and cannot long be postponed. It is a rapidly growing city, with

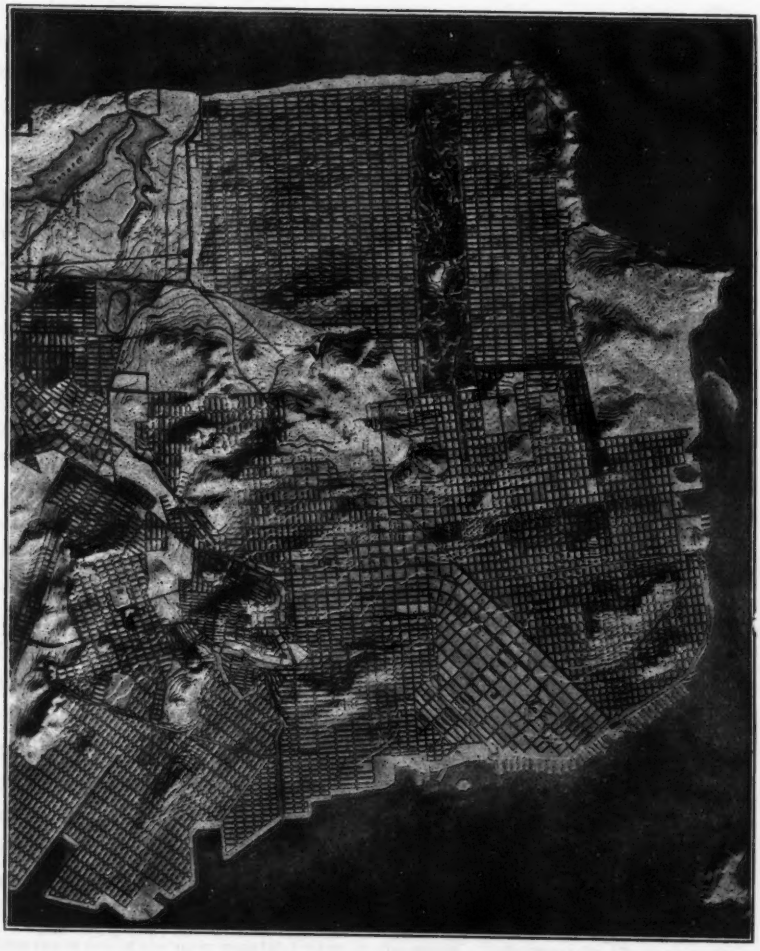

FIG. 14.—RELIEF MAP OF SAN FRANCISCO, SHOWING STREET LINES IN RELATION TO TOPOGRAPHY.

all the financial needs that this implies, yet is already surpassed in population by Los Angeles, which, 15 years ago, was not even admitted to be a rival. Its topography necessitates heavier costs for improvements than in almost any other city in America, and more to be done.* The local labor and political situation makes labor costs high. The temperament of its people makes concerted action difficult and progression slow and along indirect and expensive lines.

The outstanding indebtedness of Los Angeles is about 4% greater than that of San Francisco, with about seven-eighths the assessed valuation. However, Los Angeles owns its local water system, and has finished bringing in the Sierra supply. San Francisco, at least, will have to double its outstanding bond issue, in order to acquire the Spring Valley Water Company's properties, and the proposed completed Hetch Hetchy supply will add more than twice as much. At the best, then, to put the two centers on a proper basis of comparison, including the Sierra supply, San Francisco's bonded indebtedness would be more than four times that of Los Angeles. As to ability to care for such indebtedness in the future, Los Angeles is, in this regard, as in population, growing tremendously faster.

Under such circumstances, the real question is: Can San Francisco afford the luxury of a Sierra water supply at an immediate expense of more than 10% and a total ultimate cost of at least 16% of its present assessed valuation?

San Francisco's natural destiny as the commercial center of the Pacific Coast is beginning to be threatened. At least, until this matter is settled one way or another, San Francisco proper will be the largest and richest portion, and the natural leader of the Bay communities in this struggle.

In competition for newcomers, and in other elements causing a city's growth, is the water supply, as long as it is well above the American standard in quality and is delivered in ample quantities, at reasonable cost, and under satisfactory pressures, an aggressive and

* The topography and natural features of San Francisco are such that it could have been made one of the most beautiful cities in the world. Unfortunately, like many other places, it grew "Topsy fashion," and the layout is rectangular, quite regardless of the configuration of the land. There result grades as high as 22 per cent. The opportunity which the great fire of 1906 presented for re-designing the most important part of the city was not utilized. The City Engineer's office recently stated that $26 000 000 was the cost of certain improvements, necessary under the circumstances, but which would have been entirely avoided had the city's planning been adjusted to the topography, as might have been done, and that this expenditure was but the beginning of a series which from time to time must be made.

obvious factor, as compared with local transportation facilities, modern marine and railway terminals, paving, parks, boulevards, speedways, making areas spoiled by local development available for higher classes of city building, etc.?

Los Angeles, with 86% of the assessed valuation, as a matter of absolute necessity, has brought in a supply of 250 000 000 gal. per day from the Owens River at a cost of a little more than one-fourth of San Francisco's present programme. The quality of this water will, at best, be no better than the local supplies of San Francisco. Perhaps most important of all, however, is the fact that from the very outset, every drop of the water brought in will be used, and at prices well above the existing sinking fund and operation charges per million gallons daily. The reason that this is possible in Los Angeles, and utterly impossible as to Greater San Francisco-Oakland, is that irrigation is absolutely essential in the environs of the southern city, and irrigation water even at the city base rate of 9 cents per 1 000 gal., would be only $29 per acre-ft., which is well within the commercially feasible limit in that territory; on the other hand, in the environs of San Francisco-Oakland, little water is imperatively required, and none could be sold at even $5 per acre-ft. The fact that irrigation requirements for lands adjoining Los Angeles are practically the same as the urban needs will be when the city spreads out over them, has already been mentioned. If engineering is attaining the best results for the expenditures, this question is an engineering one of the highest type. It is the proper valuation, for a great city's purposes, of two sources of water supply.

East Bay Region.—The situation of the mainland cities is entirely different. The maximum possible development of the local water sources available would supply them for 10, or, at most, 15 years. Their distribution system, according to Mr. Dockweiler, is more than unsatisfactory, and their growth is already seriously hampered by the water situation. It would be advantageous for them, were San Francisco proper to "pull their chestnuts out of the fire." The rivalry between them and San Francisco is such that the latter would doubtless do nothing of the kind were the matter generally thus understood.

These communities face a serious situation. Their combined assessed valuation is only about $250 000 000. The ideal move would be for each section of Greater San Francisco-Oakland to acquire its

respective water system, extend and rebuild its distribution system, as the case may be, pool the local water supplies, and join in bringing in a common distant supply when necessary. Unfortunately, the local political and social situation makes such an arrangement improbable.

It is essential to realize that the water problem of Greater San Francisco-Oakland is very much more one for the mainland cities, than for San Francisco proper.

Marin County and North Bay Region.—What has been said of the East Bay cities is true of Marin County and the North Bay region, except on a much smaller scale.

VI.—Efforts Toward Municipal Ownership.

San Francisco, Oakland, and Denver are the only large cities in the United States which do not own and operate their water-works. According to present California laws, rates, extensions, financing, and service of all public utilities, outside of incorporated municipalities, are regulated by the State Railroad Commission. In November, 1914, the State will vote on the proposal to put all public utilities under the exclusive control of the Railroad Commission, and it is generally believed the change will be made.

Since 1880 municipal councils or supervisors have regulated, practically as to rates only, their public utilities. As elsewhere, this has been unsatisfactory, and at various times more or less serious steps have been taken to acquire or construct local municipal water systems.

San Francisco Proper.—The City had reports made by the late Gen. B. S. Alexander, Corps of Engineers, U. S. A., and the late George Davidson, Hon. M. Am. Soc. C. E., then of the U. S. Geodetic Survey, jointly (December, 1871); the late T. R. Scowden, M. Am. Soc. C. E. (May, 1874); and the late G. H. Mendell, M. Am. Soc. C. E., Col., Corps of Engineers, U. S. A. (1876-77). After the Mendell report the City officials tentatively offered $11 000 000 for the Spring Valley Water-Works' properties on the peninsula and the Company asked $12 500 000. The negotiations were dropped at this point.

On January 8th, 1900, a new charter went into effect, in which was declared the purpose of gradually acquiring the City's public utilities. Under it, the City Engineer at that time, C. E. Grunsky, M. Am. Soc. C. E., prepared plans for an entirely independent system, taking water from the Tuolumne River in the Sierra Nevada Moun-

tains, generally known as the Hetch Hetchy project. He estimated the cost of bringing 60 000 000 gal. per day to the Bay at $31 603 330 and the distribution system, at $8 807 000. After 12 years of effort on the part of the City the necessary rights of way, under severe restrictions, have recently (December, 1913) been granted by Congress in the passage of the so-called Raker Bill. On January 5th, 1914, the City officially accepted the grant and the conditions it carries.

In 1909 the voters passed on an alternative proposition for a bond issue of $45 000 000 to build the Hetch Hetchy project, including a distribution system, or an issue of $65 000 000 to bring in Hetch Hetchy water and buy the Spring Valley Water Company properties for $35 000 000. The latter lacked about 1 100 votes of the necessary two-thirds majority, and the former was carried.

On May 11th, 1908, the Secretary of the Interior at that time, the Hon. James R. Garfield, issued what is known as the "Garfield Permit," granting the rights of way requested by the City in the Yosemite National Park. This required the development of other portions of the project before utilizing the Hetch Hetchy Valley, a wonderful canyon of rugged beauty second only to the Yosemite Valley. On account of many protests, Secretary Ballinger, in March, 1909, acting on the advice of a committee consisting of Dr. George Otis Smith, Director of the U. S. Geological Survey, and L. C. Hill and E. G. Hopson, Members, Am. Soc. C. E., Supervising Engineers of the U. S. Reclamation Service, ordered the City to show cause why the Hetch Hetchy Valley should not be eliminated from the permit. A board of Army Engineers was appointed by President Taft, to assist and advise the Secretary in the matter. The members were Col. John Biddle, Lieut.-Col. Harry Taylor, and Col. Spencer Cosby, Members, Am. Soc. C. E. The appointment of this Board was probably due to President Taft's well-known penchant for the Army. Doubtless, none of these military engineers would urge his qualifications by training or experience as an expert in irrigation, hydroelectric, or municipal water supply matters.

At the request of the City Engineer, Marsden Manson, M. Am. Soc. C. E., Mr. John R. Freeman was called in by San Francisco to assist it in presenting its case. He associated with him eleven other members of the Society and President J. C. Branner of Stanford Uni-

versity. Afterward, M. M. O'Shaughnessy, M. Am. Soc. C. E., succeeded Mr. Manson (September, 1913), and shouldered much of the responsibility. Mr. Freeman fundamentally changed the Hetch Hetchy project as theretofore outlined.

The hearing was held by the Secretary of the Interior, the Hon. W. L. Fisher, on November 25th to 30th, 1912, and it is greatly to be regretted that the proceedings have not yet been published. The Army Board presented a report, largely the work of H. H. Wadsworth, M. Am. Soc. C. E., Assistant Engineer, Rivers and Harbors Branch, Corps of Engineers, U. S. A., on February 19th, 1913. On March 1st, Secretary Fisher decided that he was not authorized to act, and recommended Congressional action. His successor, Secretary F. K. Lane, concurred in this. Hence, there followed the introduction and passage of the Raker Bill.

On December 31st, 1913, the City of San Francisco filed suit to condemn the properties of the Spring Valley Water Company. A year before, tentative negotiations had been broken off, with the Company asking $37 500 000 and the City offering $37 000 000.

East Bay Cities.—On the mainland, Oakland and Richmond are the only communities which have made definite efforts to acquire water systems and supplies.

Oakland.—In 1902 Rudolph Hering, M. Am. Soc. C. E., made a report for a Citizens' Committee on the water supply for Oakland. He advised that 15 000 000 gal. per day of underground water could be obtained from the delta cones of Alameda Creek. In 1903, Desmond FitzGerald, Past-President, Am. Soc. C. E., reported to the same committee, and the next year a Board of Engineers, consisting of A. M. Hunt and J. M. Howells, Members, Am. Soc. C. E., and Mr. F. C. Turner, reported to the Oakland authorities on the adequacy of the Bay Cities Water Company's project for a local surface water supply from near Mt. Hamilton. A bond issue for taking over and building this project was defeated by the voters in December, 1904.

In the same year the rates of the Contra Costa Water Company (since absorbed by the Peoples Water Company), in Oakland, were fixed by the City authorities at a point so low that the Company appealed to the Courts. The result was the same as in San Francisco, namely, expensive litigation still pending and inadequate extensions of the system.

In 1910 litigation was begun between the Peoples Water Company and the City of Berkeley, but it was soon compromised by minor concessions on the part of the Company.

The formation of a municipal water district is now being considered.

The Richmond Municipal Water District.—This district was formed by an election held December 3d, 1912, covering the region bounded on the south by the Alameda-Contra Costa County Line and on the east and north by an irregular line approximating the eastern edge of the San Pablo Creek water-shed. It contains 56 sq. miles, of which 40 sq. miles, are below the 200-ft. contour. The population on June 30th, 1913, was estimated at 15 585, of which 13 575 were in the City of Richmond. The present assessed value in the district is $19 400 000.

The present daily water consumption is 3 400 000 gal., equal to 194 gal. daily per capita, of which 123 gal. are used in manufacturing and industrial pursuits. All water is pumped from underground sources, and almost exactly one-half is from private wells, the draft from which has about reached the available limit. The future per capita use will probably increase to 230, and then gradually drop to 150 gal. per day when the population reaches 150 000. Such large per capita consumption is expected because the industrial growth for many years will exceed the residence and business increase. There is no adequate fire protection.

The engineers of the district, Mr. P. A. Haviland, M. Dozier, Jr., M. Am. Soc. C. E., and F. H. Tibbetts, Assoc. M. Am. Soc. C. E., of San Francisco, have reported exhaustively on two water sources available. These are, a reservoir on San Pablo Creek, and by pumping from the Sacramento River at Toland's Landing, with an emergency intake at Antioch. The safe draft of 12 000 000 gal. daily can be secured from San Pablo Creek at a cost of about $3 500 000, and a like quantity brought from the Sacramento River, including a mechanical filtration plant, for from $4 000 000 to $5 600 000, depending on the conduit route and the materials used. The immediate development of a filtered river supply for 6 000 000 gal. daily, at a cost of from $2 300 000 to $4 100 000, depending on location and construction details desired, was recommended. The District's Board has adopted this recommendation and is arranging with

the towns *en route*, Martinez, Port Costa, and Pinole, to join in the project, and a bond election to provide funds will at once be held.

The present rates are from 30 to 35 cents per 1 000 gal., and it is estimated that, if the proposed plans are carried out, the cost will be from 20 to 25 cents, reducing in a few years, through large consumption, to 15 cents.

Marin Municipal Water District.—The present per capita water consumption is 85 gal. daily, a very small quantity for the class of urban development served. This is partly due to the actual inability of obtaining water as desired, but, chiefly to the high cost, which is 50 cents per 1 000 gal. and upward. Such high rates are in considerable measure due to the topography of the country. Early in 1912 the Marin Municipal Water District was formed, covering 115 sq. miles, in which the assessed valuation is $13 000 000. In November of that year A. R. Baker, Assoc. M. Am. Soc. C. E., was appointed Engineer, and M. M. O'Shaughnessy and Edwin Duryea, Jr., Members, Am. Soc. C. E., Engineering Advisers. It is understood that steps will immediately be taken to carry out Mr. Baker's recommendations. These are:

1.—Build a dam on Lagunitas Creek about 4 miles below the present reservoir of the Marin Water and Power Company (Lake Lagunitas), on the northern slope of Mt. Tamalpais, and create a storage capacity of 6 400 000 000 gal., or 19 700 acre-ft. In this way a daily supply of 5 000 000 gal. is expected to be obtained. The water will be taken around the shoulder of the mountain in tunnels and pipes, and delivered wholesale to the various localities from a system of main supply pipes. The total estimated cost of this first installation is $2 000 000.

2.—Take over the properties of the Marin Water and Power Company and the North Coast Water Company, and in time develop all their resources, together with the proposed new work, to the full capacity, estimated at 14 000 000 gal. daily, at a total cost of about $5 000 000.

3.—An alternative plan, not recommended, of pumping water from wells alongside the Russian River, about 25 miles from the north end of the district, and conveying it through Santa Rosa, Petaluma, and other communities *en route*, each of which would probably become customers. The cost for installations of 5 000 000 and 15 000 000 gal.

daily, from this source, would be very nearly equal to those respectively recommended.

The local distribution systems, like those of the East Bay cities, are without broad design, and leave very much to be desired, particularly in the matter of fire protection and permanency of materials.

VII.—Essential Factors Affecting a Choice of Distant Water-Supply Sources.

Far-sighted planning for a large additional supply should consider and provide for the water needs, not of the East Bay region, nor of San Francisco proper, but of Greater San Francisco-Oakland as a whole. Because there is a strong sentiment in the East Bay cities against joining with San Francisco in any political or financial enterprise, at least as long as San Francisco has a predominating influence, and because of a rapidly growing realization that in many ways the two sides of the Bay are competitive, it is possible the East Bay cities will act independently.

Quantities Required for Various Dates.—The additional quantities needed by the several portions of and for all Greater San Francisco-Oakland are about as given in Table 2.

TABLE 2.

	1920	1940	1960	1980	2000
San Francisco Proper and Southern Peninsula	10	50	100	155	200
East Bay Region	12	85	215	350	480
Marin County and North Bay Region	2	5	12	23	37
Totals	24	140	327	528	717

It will probably be economically desirable to obtain from outside sources about the quantities given in Table 3.

TABLE 3.

	1920	1940	1960	1980	2000
San Francisco Proper and Southern Peninsula	0	0	0	5	50
East Bay Region	3	46	178	312	443
Marin County and North Bay Region	0	0	1	9	23
Totals	3	46	179	326	516

Doubtless it would be profitable, certainly desirable, and at least a very nice thing, to furnish water to the urban communities along or close to the conduit or aqueduct line, and to the mutual interests of all concerned that excess water be used for irrigation along that line, until needed in Greater San Francisco-Oakland. Under existing laws, this would endanger a servitude being placed on such excess water. It must be remembered, however, that even the State Constitution can very easily be changed—especially with the initiative, referendum, and recall in effect.

Discounted Present Value Only Fair Method of Comparison.—Distant sources have the serious disadvantage that, as single-conduit installations cost much less than double or triple lines of equal capacity, larger and more expensive works than present needs demand are economically required; and interest charges on initial investments mount up startlingly. Those sources which are adaptable to gradual development have a marked advantage. Greater San Francisco-Oakland may obtain water, satisfactory as to quantity and quality, from so many different sources, that, to make fair comparisons, it is necessary to outline the expenditures of all kinds, construction, operation, maintenance, depreciation and renewals and incidental incomes, at specific dates, and reduce them to present values, using probable interest rates.

Location of Local Storage.—Another disadvantage of distant water sources is increased likelihood of damage to the conveying conduit or aqueduct. As the distance increases, other things being equal, not only is the risk of sudden interruption greater, but also the time required to make repairs, the cost of patroling, and of up-keep. To avert serious consequences in case of interruption, it is necessary to provide large, near-by storage facilities. The greater the risk the more storage is required.

Fortunately, San Francisco proper has Crystal Springs Reservoir on the Peninsula (capacity 19 300 000 000 gal., or 59 200 acre-ft.), and in a few years will have the Calaveras Reservoir (capacity 53 000 000 000 gal., or 162 000 acre-ft.), on the east side of the Bay; the East Bay cities have Lake Chabot (capacity, 4 840 000 000 gal., or 14 800 acre-ft.), with the possibility of creating the larger Upper San Leandro Reservoir (capacity, 16 700 000 000 gal., or 51 270 acre-ft.), at a cost of $3 000 000. Marin District now has Lake Lagunitas and Phœnix Lake (capacity, 382 000 000 gal., or 1 186 acre-ft.), and probably within a few years

another larger storage basin which the Marin Municipal Water District plans to build (ultimate capacity, 6 400 000 000 gal., or 19 700 acre-ft.). The location and elevation of these local storage facilities have an important bearing on the selection of a distant source.

Earthquake Zones and Faults.—The seismic disturbances which have occurred thus far in California have been *tremblors,* and not very serious matters, provided—but only provided—their likelihood is frankly recognized, the facts concerning their occurrence thoroughly ascertained, and methods to circumvent them carefully and systematically worked out. President J. C. Branner, the eminent geologist of Stanford University, urges scientific, sane, and calm study of the "active faults" in the earth's crust in California. When these are located it will be possible to build so that when future earth slips occur, the damage will be negligible. If the wriggling line of the "1906 Fault" had been accurately known, the Spring Valley Water Company would not have had its pipe line laid over it, the water supply would not have been cut off, and the disastrous fire would not have happened.

Crossings of Waterways, Bay, and Mt. Diablo Range.—There are serious natural obstacles to bringing water from distant sources into San Francisco. With the Sierra Nevadas to the east there is the wide San Joaquin Valley, the River, and the Mt. Diablo Range. The first of these prohibits a gravity line, except by using very long inverted siphons under high pressure, the last necessitating pumping against high head over the lowest pass, or long tunneling in very bad ground crossed by "active faults." To bring water from the northern Sierra Nevadas, requires crossing the narrower but equally low Sacramento Valley, the River, and the Carquinez Straits. All Sierra Nevada sources necessitate taking the water for San Francisco proper across San Francisco Bay. With southern sources Marin County can only be supplied through a tunnel more than a mile long under the Golden Gate. The water here is 300 ft. deep, and the crossing would probably be somewhat similar to the one under the Hudson River at Storm King on the Catskill Aqueduct.

Many local engineers fear the difficulties of tunneling the Mt. Diablo Range, regarding it as a formation exceedingly difficult and expensive to pierce. Mr. Freeman, on the other hand, regards the difficulties it presents as much less than those of the Carquinez Straits

crossing, which latter he regards as offering such tremendous obstacles alone as to dismiss immediately from serious consideration all sources which would involve it.

Conservation.—There can be no doubt that supplying municipal needs is the highest use to which water can possibly be applied. That is by no means saying that other useful requirements should not be considered at all until such highest use is fully satisfied. All needs of a region should be considered in relation to all supplies, and adjustment made to secure the maximum total economic benefits to society. This is so obvious that taking the trouble to state it seems waste of time. Nevertheless, it is usually adroitly ignored and avoided for the reason that the greatest total benefits to society may mean individual lesser benefit or greater cost to a powerful interest. The total benefits and costs are rarely divided in like proportions. To this fact is due conservation and the conservation policy—now generally accepted in theory and almost as generally sought to be avoided in individual cases.

In California, as in all the Far West, because of climatic conditions, water is more important than fertile soil and strategic position. The water resources of the Central Valley and the northwestern part of California, sooner or later, will be so conserved and apportioned as to produce the maximum possible benefits. No use can be so high as to interfere permanently with, or prevent, such a result. Unfortunately, no definite steps have yet been taken toward such end, and this fact alone seems to justify the National conservation movement. It is extremely unsafe, however, for any interest to assume that such indifference will continue. The world moves and, in the Far West, it moves rapidly. Indeed, it is startling to look back only 10 years and see how the viewpoint of the general public has changed with regard to the exploitation of natural resources and how it has already been crystallized into fundamental changes in legislation. Any person, corporation, or municipality is most short-sighted to make investments without weighing carefully the probable changes in public opinion and consequent legislation, designed to produce a higher degree of intrinsic justice—at least for the period necessary to "unload" successfully.

Furthermore, municipalities are but mutual corporations. In Wisconsin, municipally owned public utilities have for years been regu-

lated as to service, rates, and accounting, exactly like privately owned and operated utilities; and Wisconsin's lead in such matters has been closely followed in the Progressive West.

Irrigation.—Next to municipal use comes irrigation. In discussing the growth within California, the agricultural history of the Central Valley has been touched on and the radical changes at present under way noted. The American, and particularly the western, characteristic attitude toward experience elsewhere, resulted in irrigationists having to learn by bitter experience the wisdom of the United States Reclamation Service's standard of satisfactory irrigation water supply. This standard is that all water users have ample water at all times when it can be used profitably. It involves storing flood-waters for use when streams are very low or entirely dry during the latter part of the summer. The California Central Valley has been almost the last part of the United States to find itself in this regard.

The tremendous value of the climate and fertile soil in the great Central Valley is still not appreciated. The crop adaptation is marvelous. It is conservative to say that 20 years hence an acre of properly irrigated bare land anywhere in the Central Valley will be worth at least $500, and citrus land in the foot-hills from $600 to $800. It is equally conservative to say that in the central and southern parts of the San Joaquin Valley, particularly, unirrigated agricultural land will be worth not more than from $20 to a possible maximum of $50 per acre.

Power.—Next in order of use is the development of hydro-electric power. California stands near the head of all States in the quantity of developed water-power, and yet only a fraction of its possibilities has been utilized. The cheapest fuel is oil from local fields, now costing about 75 cents per bbl., wholesale, equivalent to coal at $3 per ton, and the supply is by no means limitless. The tremendous economic importance of the power resources of the State is obvious.

The difference between the ultimate value to society of a natural resource and the commercial value of a development of that resource must be understood. Local and general economic conditions have resulted in smaller hydro-electric concerns gladly disposing of their output in blocks at high load factors to the large companies for about ½ cent per kw-hr. One of the largest power corporations in the State, with hydro-electric plants scattered for miles along the western slope

of the Sierra Nevadas, transmission lines gridironing the central part of the State, and a 60% load factor, is generating more than 40% of its energy in steam plants.

Indeed, there is a general misconception of the commercial value of "water rights." Every decrease in cost and increase in efficiency of steam plants reduces the relative advantages of water power. The steam turbine is a notable example. The "value of water rights" has lowered tremendously in the past few years, because of rate and service regulating commissions. The tendency is to regard a water right, not as an asset, but as an exclusive license for self-constituted trustees to develop a public resource and operate it for the benefit of the public, on a percentage. This change of sentiment has practically wiped out the commercial value of a proposed project controlled by a "water filing." Companies doing a tremendous business and having ample credit can wisely carry out enormous developments and secure thereby very low costs per unit of installed capacity. The rapid development and constantly lowering cost of electric generating and transmitting equipment and the progress of the art in general are other important factors.

For example, one of the recent large projects in the State, now more than half completed, is a development in which water will be dropped through six power-houses and generate 165 000 h.p., with a total cost of $130 per installed kw. or $97 per h.p. Even this will be reduced, because water from the lowest plant will irrigate a large body of land and the State Utility Commission will certainly take irrigation water rentals into account in fixing power rates. Obviously, such developments affect the value of all hydro-electric plants and projects looking to San Francisco as a market, if not throughout the whole State.

This matter has been considered at length because the Army Board evaluated the "incidental power possibilities" of the Freeman Hetch Hetchy project—115 000 h.p.—at $51 100 000. This is more than $445 per h.p. On such a basis, the water rights of the power company's complete development, just mentioned, would have to be $37 425 000. A completed hydro-electric installation feeding into a completed transmission system supplying an actually developed market, is probably worth not more than $125 per h.p.—without such market, particularly, and the means of serving it, much less. Los

Angeles is discovering this in connection with its aqueduct power, as the city itself finds it impossible to use the hydro-electric power at a high average load factor.

Navigation.—The Sacramento River is technically navigable to Red Bluff and the San Joaquin River up to Firebaugh. Both streams are much used in the lower stretches—the former to Sacramento and the latter to Stockton. Beyond these latter points navigability is at present important chiefly on account of holding down local railway rates. Consequently, navigation in this case ranks below irrigation and power uses.

Obviously, any water storage which increases the natural flow at low-water stages improves navigation. Diversion from tributaries and upper reaches of main streams for irrigation is usually, though not always, conflicting. Diversion from higher areas, entirely outside the water-shed, as a supply for Greater San Francisco-Oakland, would always be conflicting, though, with some sources, with very small low-water flow, negligibly so.

In the Sacramento Valley there are several available storage possibilities by which the flow of the Sacramento River at Red Bluff could be increased by 500 sec-ft. for 4 months, and numerous ones to provide such increase below Marysville. In this way, navigation interests could easily and relatively cheaply be protected to permit diverting enough water from any part of the Valley drainage to supply Greater San Francisco-Oakland.

In the San Joaquin Valley the situation is not so fortunate. There the water supply is so deficient, except possibly in the northern end, that the use of storage opportunities in this way cannot be afforded.

Flood Protection.—Last of all—so far as storage is concerned—comes flood protection. The 1 750 000 acres flooded in the Central Valley must always be protected by levee systems almost exclusively. Of course, storage for almost any use would help.

Senator Newlands, the author of the Reclamation Service Act, has recently introduced a bill in Congress providing $60 000 000 per year for 10 consecutive years for flood protection, of which one-twelfth is for the Sacramento and San Joaquin Rivers, and the California Reclamation Board has outlined a $50 000 000 project for the Sacramento Valley. Spending such tremendous sums for reclaiming

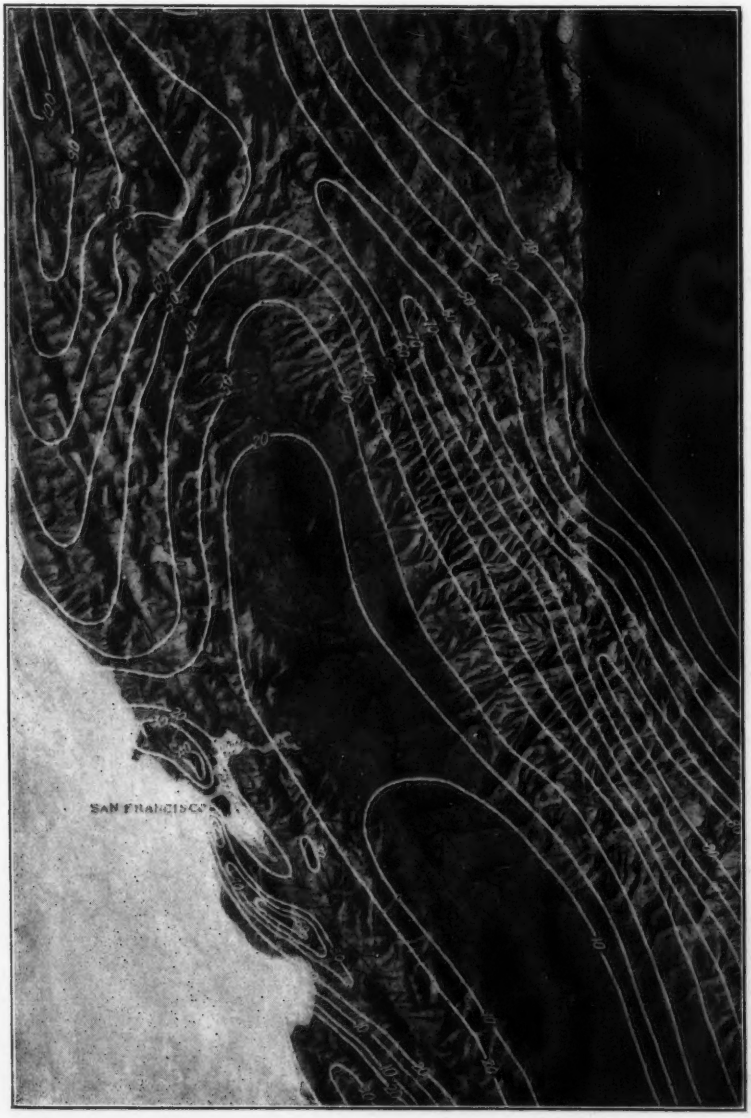

FIG. 15.—RELIEF MAP, SHOWING PRECIPITATION OVER CENTRAL CALIFORNIA.

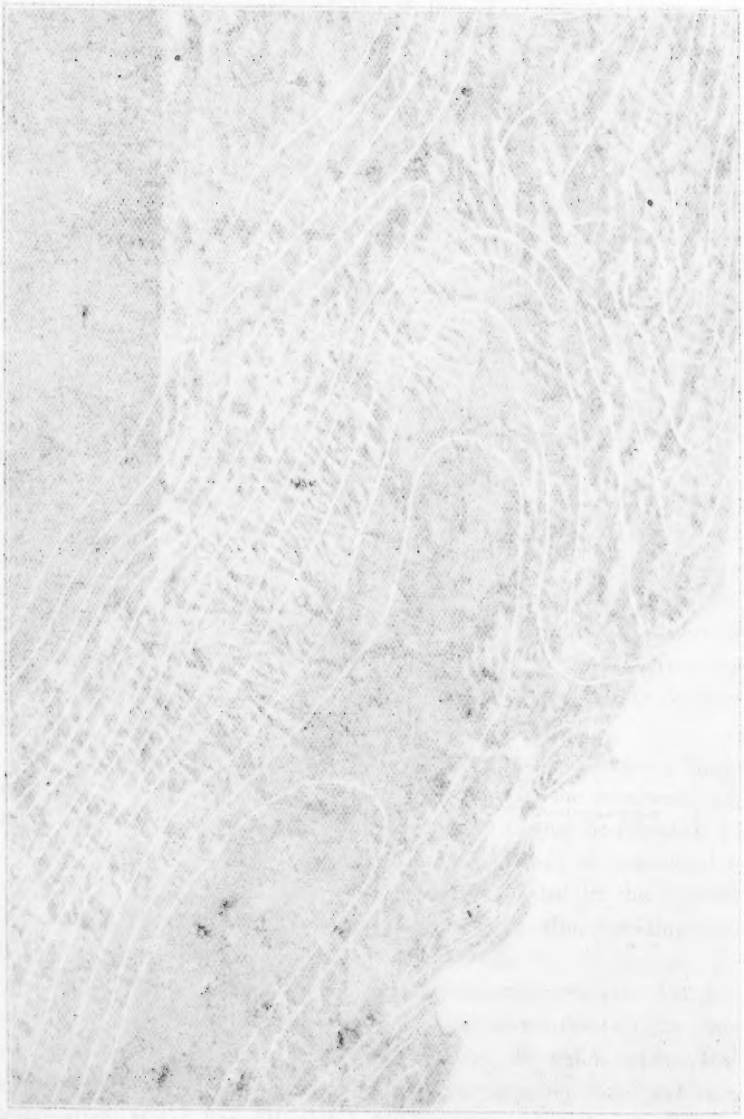

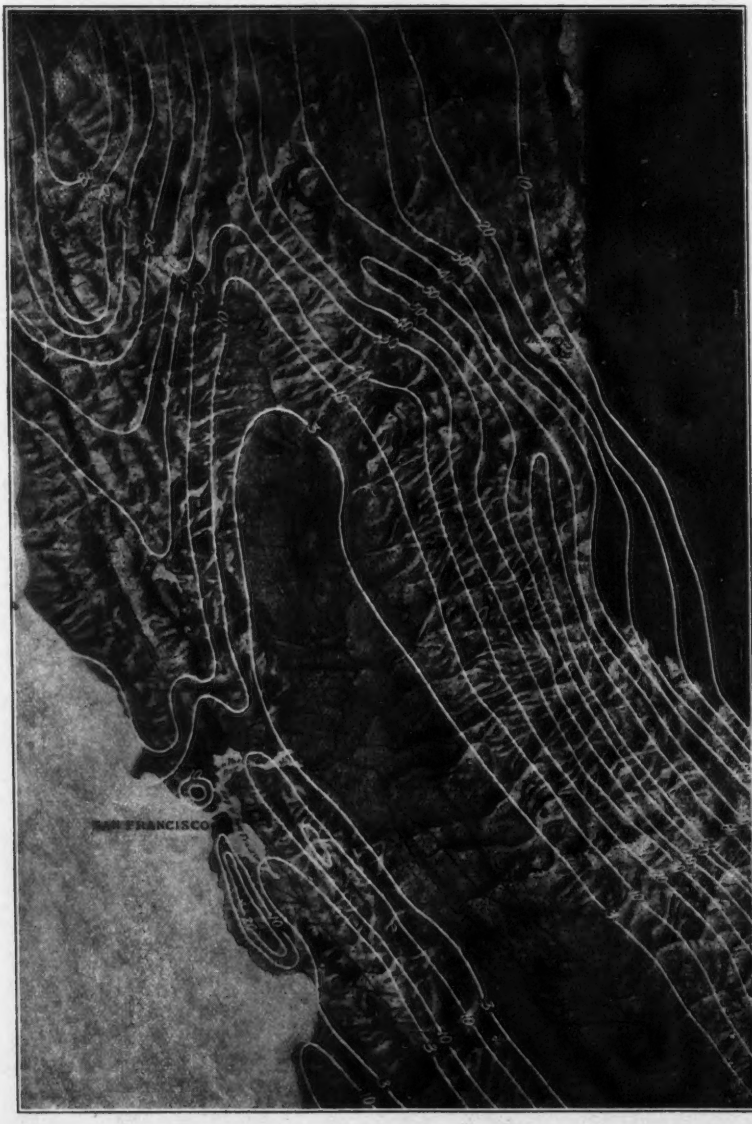

FIG. 16.—RELIEF MAP, SHOWING RUN-OFF OVER CENTRAL CALIFORNIA.

bottom-lands and neglecting to prevent waste of such citrus lands through unwise distribution of water resources is foolish.

All Uses Interwoven.—All these utilizations of the Central Valley's water resources are inter-dependent. To secure the greatest total benefits to society offers no serious problems in statecraft or engineering —only an intelligent general plan. In some sections there will then be water to waste, in others a deficiency. In any event, all comers, no matter of how high or of how low degree, or of what precedence their claims, will sooner or later be made to conform with such a general plan.

California Precipitation and Run-Off.—Figs. 15 and 16 show the probable mean precipitation and run-off curves for the State, based on all the data yet collected.

It is more than unsafe to design hydraulic works in California from mean annual figures, because of dry cycles often 6 and 7 years long. The precipitation, speaking generally, is due to storm centers coming over the Pacific Ocean and passing on to the east. When the center enters the United States near Puget Sound, practically no precipitation results in the southern half of the State, but when the path lies farther south, say, at San Francisco, the entire State receives rain. For some reason these storms often pass well to the north for several successive years. Each year in addition, there are usually three or four relatively unimportant storm centers which pass over or near San Diego. Nevertheless, it is said that the records, kept by the Franciscan Fathers at the Mission in Santa Barbara for more than 130 years, show 1 year with absolutely no measurable precipitation.

As a consequence, in the southern end of California all significant storms are general, and in dry years so gentle and distributed that the percentage of run-off is almost incredibly small. Going northward, such conditions are less noticeable, but, throughout the entire State, especially as far north as Sacramento, long dry-year cycles frequently occur.

There are few run-off data in California prior to 1901, when the State and the U. S. Geological Survey began co-operating in systematic stream gauging. There are shorter cycles of dryer years before this period, however. This fact must be kept in mind in connection with the run-off curves given. For example, one would make a grievous

mistake by using all the stream gaugings after 1902 in Fig. 17, and assuming them to be typical. There were few reservoir records prior to 1901 in the Sierras, like those at Sweetwater and Cuyamaca.

Irrigation Water Requirements.—In determining the excess, if any, of available water above the needs for irrigation in any territory, there are the two factors, irrigable area and the local duty of water. The first is simply measured, except that in some cases the greatest utilization of a large region's water resources may require modifying the natural limits, such as water-sheds.

The local duty of water, however, is as yet a matter of judgment. It varies with soil types, present and future crops, drainage, character of supply, metered or unmetered service, and extent of cultivation. Very little Middle and Northern California data are enlightening, because very few supplies are really what they should be. Water rentals on a quantity basis are the rare exception. The almost universal disposition of irrigators to use too much water is well known. Few supplies are dependable, particularly during the latter part of the irrigating season, when streams are at the lowest. This results in using excessive quantities during times of plenty, to store water in the soil, a wasteful plan, unsatisfactory in many ways. Thus water-logging and temporarily ruining large areas is the general experience in almost all western irrigation projects. Averages of current practice, therefore, are thoroughly unsafe guides; the extreme limits are too far apart.

The various State Agricultural Experiment Stations and the U. S. Department of Agriculture have made numerous experiments to check such collected data. Unfortunately, these data do not have great practical value, just as the results of acceptance trial tests on steam-power plants are not safe bases for estimating output cost per horse-power per annum.

An important economic factor is the degree of soil cultivation. When the Sweetwater Reservoir was empty and the precipitation very small, citrus trees near San Diego were kept alive with only 3½ in. of irrigation water per annum, but at a cultivation cost normally prohibitive. Dry farming could be practiced successfully over vast areas where it is economically unjustified under conditions now and for a long time obtaining. The two greatest problems in America are to stop the disproportionate growth of cities and to improve the labor situation on the farm. Assuming that 1 acre-ft. of water per

annum and a cultivation cost of $25 per acre will produce as much as 3 acre-ft. of water and a cultivation cost of $5 per acre, is the water saving justifiable? Except where the water supply must be extended

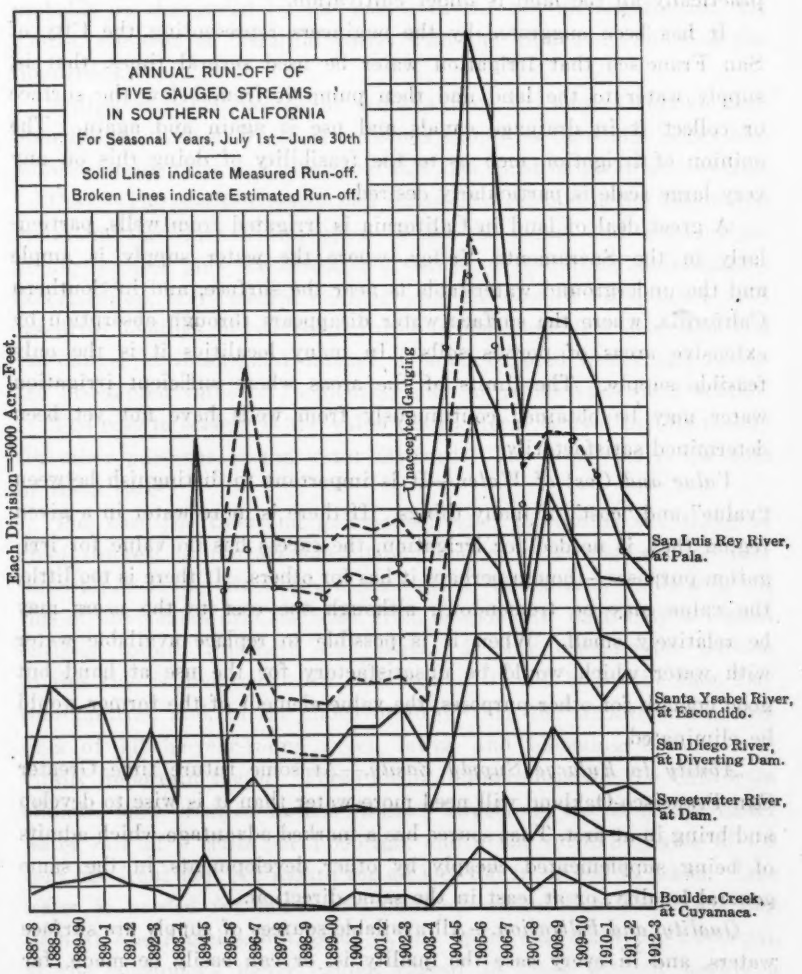

FIG. 17.

over exceptionally valuable land, obviously it is not. Experimental or theoretical and economical minimum water duties are very different things.

Many irrigation engineers believe the only safe guide is the actual water use over large successfully cultivated areas where conditions are essentially similar, where the water supply is metered, and where practically all the land is under cultivation.

It has been suggested by the engineers representing the City of San Francisco that irrigation water be used several times, that is, supply water to the land and then pump it from below the surface or collect it in drainage canals and use it again and again. The opinion of irrigation men as to the feasibility of doing this on any very large scale is particularly desired.

A great deal of land in California is irrigated from wells, particularly in the Sacramento Valley, where the water supply is ample and the underground water-table is near the surface, and in Southern California, where the surface water disappears through absorption by extensive areas of porous soils. In many localities it is the only feasible supply. The limits of the areas where sufficient irrigation water may be obtained continuously from wells have not yet been determined satisfactorily.

Value and Cost of Water.—It is important to distinguish between "value" and "cost" of many things. If there is more water in a given region than is needed for irrigation, the excess has no value for irrigation purposes—though perhaps it has for others. If there is too little, the value may be tremendous, although the cost to the users may be relatively small. When it is possible to replace available water with water which would be unsatisfactory for the use at hand but good enough for other purposes, the value element of the former would be eliminated.

Ability to Enlarge Supply Easily.—At some future time Greater San Francisco-Oakland will need more water than it is wise to develop and bring in at first. That source has a marked advantage which admits of being supplemented cheaply by other developments in the same general locality, or at least in the same direction.

Quality, and Filtration.—All available sources of supply are surface waters, and in every case the quality is, or can easily be made, far above what is generally regarded as satisfactory for large cities. Some are better in this regard, others in that; some will require immediate filtration, with others it would be unnecessary. The disposition is to insist more and more on treatment of all surface supplies, even when long

storage in reservoirs is possible. Quality standards in everything are rising, and filtration to remove coloring matter and minute organisms, even when, for hygienic reasons alone, it would be unnecessary, will probably be demanded by the public in the not distant future. Of course, the cost of filtration varies with the kind and extent of the impurities.

Sentiment.—The people of Greater San Francisco-Oakland have been taught to regard a Sierra Nevada supply as markedly better and more desirable than any other, and this fact must be given due weight.

Cost.—The cost to Greater San Francisco-Oakland is the discounted values of the expenditures required for the rights and construction of any project plus the discounted values of operation, maintenance, deterioration, and renewal charges, plus the cost of antagonistic and resentful feelings of all communities which may feel despoiled and the danger of intentional damage to much-exposed works, and minus the discounted value of incidentals such as power and water rentals.

The cost to society is the value (as the term is used in this paper) for other purposes of the water diverted. The total cost is the sum of these two.

The cost per thousand gallons delivered to him is the thing of chief interest to the average citizen, and of particular and peculiar importance to the East Bay communities. As already explained, the tide of newcomers into the State from east of Salt Lake City is almost entirely toward Southern California. If any considerable portion of this tide is diverted to the Bay regions, it will be by the East Bay communities, and, in the endeavor to do this, the striking attractiveness of all-the-year-round green lawns and blooming flowers is a vitally important factor. These media, all accentuating the California climate, have resulted in Los Angeles largely by reason of the meter water rate of 9 cents per 1 000 gal. and a flat sprinkling rate of 0.9 cent per front foot per month for all lots 150 ft. or less in depth. Less water is needed for lawns and gardens around San Francisco Bay than at Los Angeles, but, even so, the upper cost limit per 1 000 gal. at the consumer's meter cannot exceed 15 cents without having a serious effect on the area of lawn in the East Bay district.

It is a luxurious thing to have a high mountain water supply, but it is not an obvious point in competing for the Eastern and Middle West newcomers to the State. In this day and generation, to urge a

pure water supply is about as impressive as to dilate on satisfactory police protection, or paved streets—these things are assumed as a matter of course. Green lawns and blooming flowers the year round, and especially in winter, made possible by California's distinctive climate, is constantly impressive to to-day's tourists and to-morrow's fellow-citizens, and these features must be practically universal to compare at all favorably with the southland.

It is a simple matter to take a base rate of 15 cents per 1 000 gal., meter measurement, the present or prospective consumption at any given time, the cost of operation, taxes, etc., and, with any assumed rate of interest, ascertain the capital investment which may be expended on water supplies without jeopardizing this matter of lawn development. Suffice it to say that any proposed water development on a large scale, which would make water cost more than 50% greater than the rates obtaining in Los Angeles, is practically beyond the means of the East Bay cities. This point is of little importance in San Francisco, because there are notably few and small lawns, and even with free water from now on, that city never could be made comparable in that way with Los Angeles.

VIII.—Possible Distant Sources of Supply.

The following additional sources of supply have been suggested: Eel River, Putah Creek, and Clear Lake and Cache Creek, from the northern Coast Range region; Sacramento and San Joaquin Rivers, from the delta region of the Central Valley; and McCloud River, Indian Creek, Feather, Yuba, and American Rivers, Lake Tahoe, Mokelumne, Stanislaus, and Tuolumne Rivers, from the Sierra Nevadas.

A.—Coast Range Sources.

The Coast Range sources are shown on the map, Fig. 18. The water is not needed locally for irrigation. The length of conduit is much less than that for any of the Sierra Nevada sources, and, as a supply for only the East Bay cities and Marin County, is apparently well worth more careful consideration than it has received. In the construction of the project, the Carquinez Straits crossing should be made sufficiently large to serve as well for the maximum possible additional supplies, such as the McCloud, the Indian Valley, and the Feather River projects, when any or all of these may be needed.

FIG. 18.—RELIEF MAP, SHOWING POSSIBLE COAST RANGE SOURCES OF SUPPLY.

FIG. 19.—RELIEF MAP, SHOWING POSSIBLE NORTHERN SOURCES OF SUPPLY.

SAN FRANCISCO

Eel River.—Above the Gravelly Valley Reservoir site, where 180 000 acre-ft. capacity could be created by a dam 140 ft. high, is a drainage area of 326.5 sq. miles. The safe draft is estimated at 180 000 000 gal. daily, or, with a conduit of 225 000 000 gal. daily capacity, and using the large terminal storage in Greater San Francisco-Oakland, 200 000 000 gal. daily. The conduit would be so near the hydraulic grade line that reinforced concrete pipe could be used for much of the distance. The elevation of the intake is 1 000 ft., and the length of the conduit to San Francisco, *via* Golden Gate, 125 miles. No cost estimates are available.

Putah Creek.—Putah Creek is the closest mountain source. With the excellent Monticello and Guenoc Reservoir possibilities, a safe draft of about 150 000 000 gal. daily could be secured. The conduit could follow closely the hydraulic grade line to Carquinez Straits and be 60 miles long to Lake Chabot, back of Oakland. The water should all be used locally for irrigation.

Cache Creek and Clear Lake.—Within the possible limits of lake-level regulation, 600 000 acre-ft. of storage could be obtained in Clear Lake, with which a safe draft of about 195 000 000 gal. daily would be possible. This water would not be of the best, and it should all be used for irrigating tributary valley and foot-hill land.

B.—Delta Sources.

The Delta sources are shown on the map, Fig. 20.

San Joaquin River.—The low-water flow of the San Joaquin River is so small that an intake would have to be constructed where inflow from the Sacramento River could be assured, and yet be high enough to avoid salt water from the Bay. Mr. Wadsworth suggests Clifton Court on the Old River. The supply would have to be filtered. The Sacramento River water is clearer, of better quality, softer, has less mineral matter, and a much less seasonal variation.

Sacramento River.—At the mouth of the Sacramento River the water becomes slightly brackish late in the seasons of low run-off. At Toland's Landing, 5 miles above, it is always fresh. In the future, increased irrigation use will tend to reduce the flow during the early part of the season, but will probably slightly increase the low-water flow, though storage for power development and other purposes will materially increase the low flow. It is highly improbable that sea

water will ever get materially farther up stream than at present. Mr. Allen Hazen reported in 1912 that the "Sacramento River water be filtered so as to produce a good potable water at all seasons of the year, removing the turbidity, color, and results of sewage pollution." The resulting hardness would be from 56 to 62%, or about two-thirds that of Washington, Cleveland, Chicago, Pittsburgh, Cincinnati, or Louisville, and 80% more than New York or Philadelphia.

The filtration plant and an emergency intake would be near Antioch, as planned for the Richmond Water District. The total length of the line recommended by Mr. Hazen, starting about 8 miles farther up the river, at Rio Vista, running thence directly to filtration works at Antioch, and thence to Walnut Creek, East Oakland, Alameda, and across the Bay to Potrero Point, San Francisco, is about 54 miles.

Estimates on this project were with a $3 wage scale for an 8-hour day and present railway freight charges on material from the East. Taking dates for installations of 133 333 333 gal. daily, except tunnels built originally for 400 000 000 gal. daily capacity, as 1914-18, 1936, and 1975, respectively, interest at 4½%, and assuming that all plants would begin running at capacity immediately on installation, at a cost of $17 per 1 000 000 gal. for operation, maintenance, depreciation, and renewals of plant, the present value of the cost of this source is estimated by Mr. Wadsworth as $51 700 000.

Doubtless, no one would seriously consider installing works of 133 333 333 gal. daily capacity for a community now fully supplied and using only 70 000 000 gal. daily, nor begin to operate them to full capacity immediately on completion. Caution must be used, therefore, with this figure of $51 700 000.

The water diverted would have no value for any other purpose whatever. No power could be generated, and practically no water sold *en route*.

C.—Sierra Sources.

The Sierra sources are shown on the map, Fig. 21.

McCloud River.—The McCloud River rises on the south side of Mt. Shasta, and, joining with the Pit River, forms the principal tributary of the Upper Sacramento River. It has a remarkably steady flow for California, and a minimum discharge of 1 200 sec-ft., or 770 000 000 gal. daily—amply sufficient for all possible needs. The quality is excel-

FIG. 20.—RELIEF MAP, SHOWING POSSIBLE DELTA SOURCES OF SUPPLY.

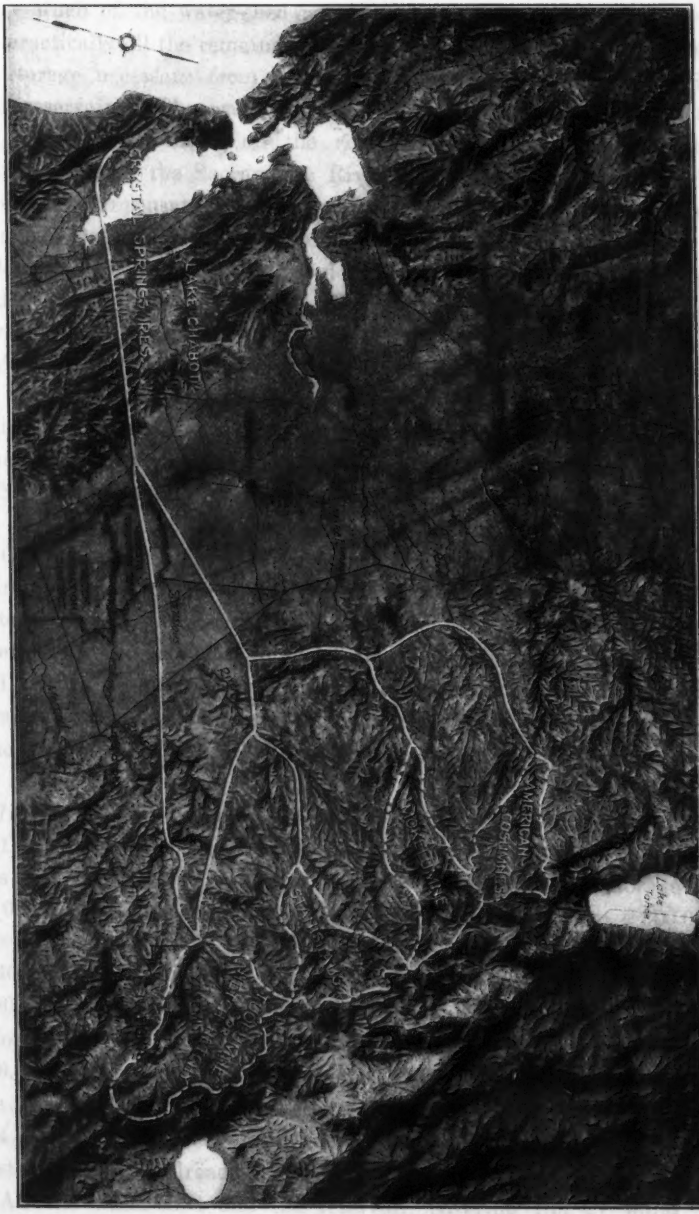

FIG. 21.—RELIEF MAP, SHOWING POSSIBLE SOUTHERN SOURCES OF SUPPLY.

lent. Much of the water-shed is in the Mt. Shasta National Forest, and practically all the remainder, 400 000 acres, is offered for $3 000 000. All storage necessary from hygienic considerations could be had in local reservoirs. The water is not needed for irrigation, and there are storage possibilities on the river itself and elsewhere in the drainage area of the Sacramento River above Red Bluff which would more than compensate for any purpose for any quantity Greater San Francisco-Oakland could wish to divert during low-water stages. It is doubtful whether the City would ever have to do anything of the kind—certainly not for years. The comparison of this with other Sierra Nevada sources is thus practically one of cost only.

An aqueduct to Lake Chabot, in Oakland, would be 212 miles long. Mr. Wadsworth's estimate for the discounted present value of an initial installation of 260 000 000 gal. daily, 1914-20, and an additional 140 000 000 gal. daily, in 1973, is $52 500 000.

No power would be developed along the aqueduct line, but, on the project and within the controlled tributary water-shed, about 130 000 h.p. can be developed at attractive costs. The conduits, almost entirely of gravity type and of reinforced concrete, would be along the western edge of the Sacramento Valley for the entire length of the latter, and would pass close to many rapidly growing towns and irrigable land having the highest crop and fruit adaptation in the State. All excess water could doubtless be sold along the way from the very start, although not at prices fully proportionate to the cost of the aqueduct and reservoir system.

Indian Creek.—Indian Creek is a branch of the North Fork of the Feather River, with one of the best and most economical reservoir sites in America. A dam 120 ft. high would create a storage of 600 000 acre-ft. and one 220 ft. high and 900 ft. long on top, 2 300 000 acre-ft. (a capacity of 445 000 acre-ft. is equivalent to a yearly flow of 400 000 000 gal. daily). The flow line would have an elevation of 3 680 ft., and the area would be 11 500 acres. The mean annual evaporation is about 3½ ft. The run-off has been gauged from January, 1906, to date, except from January 1st, 1909, to September 10th, 1911. The average annual discharge seems to be about 480 000 acre-ft. The dam site is 4 miles, by good automobile road, from Keddie on the Western Pacific Railroad.

All the water-shed and the reservoir, covering 733 sq. miles, is

in the Plumas National Forest, and, except a total of 30 000 acres, which would cost about $1 100 000, is public land. There would be no interference with irrigation or navigation, and fewer legal entanglements than with any other Sierra Nevada or Coast source, except possibly the McCloud. A total development of 140 000 continuous horse-power is possible with the final tail-race at Elevation 1 000. It has recently been investigated by the California Débris and the Conservation Commissions for flood control. It will doubtless soon be used for hydro-electric development. It has no proponents, and no surveys or estimates as a supply for Greater San Francisco-Oakland have ever been made. The conduit line to Lake Chabot would be about 196 miles long.

By State legislation, this opportunity could be held indefinitely available for future use, at no expense except the economic waste resulting from preventing power development below 1 000 ft. elevation. The McCloud Project conduit line would be followed for about half the distance, the Yuba River conduit line would be common for most of the way.

Feather River.—The water-shed of the Feather River is characterized by steadiness (for California) and quantity of run-off, and by great storage possibilities. There is no doubt that it could furnish more water than Greater San Francisco-Oakland will ever need, in addition to all possible irrigation requirements. Unless the intake were at one of the large reservoirs in the head-waters, such as Indian Valley or Big Meadows, the purifying effect of storage would be offset by mixing with run-off from areas almost but not wholly uninhabited. If the supply is to be filtered, the lower Sacramento River, except in point of hardness, is more advantageous.

Yuba River.—There is little natural storage on the Yuba water-shed, except at the highest part of the South Yuba drainage area, therefore the run-off is rapid and irregular. By a system of natural and artificial reservoirs on the South and Middle Forks, a daily supply of 165 000 000 gal. of suitable water could be obtained at reasonable cost. This could be well adapted to a combination with water from some portion of the Feather River Basin, or other sources. The water is always more or less turbid. By making a diversion near the mouth, 400 000 000 gal. daily could be secured, but at so low an elevation

that pumping would be necessary and filtration advisable. Less than one-half the quantity could be spared by irrigation interests.

All these Sierra Nevada sources would be brought into Greater San Francisco-Oakland from the north, the conduits crossing Carquinez Straits. This, according to Mr. Wadsworth, would require 5 300 ft. of tunnel and 600 ft. of shafts, and would cost $1 150 000. Piercing the Mt. Diablo Range would be avoided. With the sources following Fig. 21, there would be no crossing of Carquinez Straits, but the Mt. Diablo Range would have to be passed.

American River.—The American River enters the Sacramento River at Sacramento. The Cosumnes, a tributary of the Mokelumne River, lies just to the south, and, owing to the topography, the upper and contiguous portions of the two water-sheds have usually been considered together in outlining power and water projects. A daily supply of about 230 000 000 gal. of excellent water can thus be obtained at reasonable cost, and diverted out of the valley without important injury to dependent irrigation interests. Approximately 62 000 net continuous horse-power could be developed incidentally.

Lake Tahoe.—Lake Tahoe is only mentioned because it seems naturally to suggest itself to many. It can supply daily about 275 000 000 gal. of excellent water, but all of it and much more is needed for the Nevada desert, where, logically and properly, it should be used.

Mokelumne River.—It is estimated that from the Mokelumne River a daily supply of from 130 000 000 to 150 000 000 gal. of satisfactory water could be secured. It is said that a storage of 250 000 acre-ft. is about the limit which can be developed on the water-shed, and that there are 200 000 acres of irrigable land dependent on the stream for water. In such case it is very doubtful whether it would not be against the best interests of society to divert out of the water-shed for any purpose more than half such quantity, or possibly any at all.

Stanislaus River.—Before getting even as far south as the Stanislaus River, the excess of water over satisfactory irrigation requirements has become very small, and here probably passes through zero and becomes minus. By taking into account the water due others by appropriations, it has been computed that about 60 000 000 gal. per day could be diverted out of the water-shed. The present water laws of California are little less than absurd, and it is most short-sighted to stop with them. Taking into account ultimate irrigation

needs, instead of rights, it is improbable that any water is properly available.

Tuolumne River.—The Tuolumne River is the source selected by Mr. Grunsky, City Engineer in 1901, and, because it contemplated transforming the famous Hetch Hetchy Valley into a reservoir, is generally known as the Hetch Hetchy supply. Mr. Grunsky proposed to bring in 60 000 000 gal. per day. In 1912 Mr. John R. Freeman increased the quantity to 400 000 000 gal. per day, or 618 sec-ft., and, among other results, was crystallizing opposition of local irrigation water users and securing by them conditions protecting many of their interests.

The Raker Bill, which Congress recently (December, 1913) passed, granted San Francisco the necessary reservoir, conduit, and other rights of way in, over, and through certain public lands, the Yosemite National Park, and the Stanislaus National Forest. Following the methods of the Conservation Policy, the grant requires:

1.—Filing customary maps, observance of National Park and Forest rules and of prior valid claims, etc.

2.—No sanitary regulations over the water-shed, other than as enumerated (those necessary in any event to protect campers in the Park from having polluted water to use).

3.—Recognition by the City of the prior right of the Modesto and Turlock Irrigation Districts (acreage not to exceed 300 000) to 2 350 sec-ft. of the natural daily flow at La Grange, whenever said districts can beneficially use it, and to 4 000 sec-ft. between April 15th and June 14th.

4.—The City to sell "such amounts of stored water as may be needed for the beneficial use of the said irrigation districts" at cost, with maximum and minimum quantities thereof which can be demanded during any calendar year. These quantities are to be fixed and occasionally revised by the Secretary of the Interior.

5.—The City not to divert out of San Joaquin Valley water for other than domestic and other municipal purposes.

6.—It defines "natural daily flow" as the quantity which "on any given day would flow in the Tuolumne River or its tributaries if said grantee had no storage or diversion works on the said Tuolumne water-shed."

7.—The immediate building of Hetch Hetchy Dam, 200 ft. high, and with a base "capable of supporting said dam when built to its greatest economical and safe height."

8.—The City to sell at cost electric power to said irrigation districts and municipalities within them.

9.—The installation by the City of 10 000 h.p. within 3 years of completing "any portion of the works adapted to the generation of electrical energy;" 20 000 h.p. within 10 years; 30 000 h.p. within 15 years; 60 000 h.p. within 20 years; and all additional possible power as soon thereafter as ordered by the Secretary of the Interior.

10.—The City to construct and forever maintain scenic roads and trails (estimated first cost $1 000 000).

11.—The City, after 5 years, to pay the Government $15 000 annually for 10 years, and thereafter $30 000 annually.

12.—The City to pay all costs of investigations or decisions required under the Act to be made by the Department of the Interior.

13.—The City to convey all its lands in the Yosemite National Park and the Stanislaus National Forest to the United States.

14.—The City to sell water at cost to the United States War Department in or near San Francisco.

The City of San Francisco formally accepted this grant with all these conditions on January 5th, 1914.

Under the Raker Bill, it is impossible to estimate closely either how much water San Francisco may divert or the cost of doing so. It is to finance the complete conservation of the water from the entire water-shed above La Grange and receive thereby the excess over local irrigation needs. The City assumes all the uncertainties. These are:

1.—Quantity of water needed for beneficial use by the 300 000 acres of land during critical years. Opinions vary from 600 000 to 1 050 000 acre-ft. per annum.

2.—Quantity of stored water needed for the beneficial use of the Irrigation Districts.

3.—Quantities the Secretary of the Interior will consider proper for the annual maximum and minimum quantities of stored water the City must furnish. This will be determined by the results of experience in the matter, and by public sentiment at that time, as reflected by the Secretary of the Interior, regarding the propriety of the City

having insisted on going for its water supply to a region where there is a deficiency instead of an excess.

4.—The available storage capacity in the water-shed. This has been usually taken at 800 000 acre-ft. The U. S. Geological Survey adopts 1 000 000 acre-ft. Mr. O'Shaughnessy, the present City Engineer, estimates it as 1 800 000 acre-ft.

5.—Quantity of run-off at the various reservoir sites and diversion points during critical years.

6.—Quantity of storage which the power projects and the irrigation districts will provide without cost to the City.

7.—Construction, depreciation, and operation cost of an undetermined quantity of storage.

The amount which, if invested at 4½% compound interest, in 1914, would construct the Freeman Hetch Hetchy project is estimated by Mr. Wadsworth as $38 901 000. This contemplates the initial installation of 160 000 000 gal. per day, 1914-20 (mean date 1917); 80 000 000 gal. per day additional, 1945-47; and 160 000 000 gal. per day additional (total 400 000 000 gal. per day), 1963-69.

These figures must be used cautiously, however, because:

1.—The City has revised the estimated cost of the first 160 000 000 gal. per day installation from Mr. Freeman's figure of $37 501 400 to about $64 000 000, and probably the figures on the other installations as well.

2.—No renewals of relatively short-lived constructions have been taken into account. There are about 100 miles of steel pipe, much of it under heads as high as 800 and 900 ft.

3.—The Freeman Hetch Hetchy project and the Raker Bill Hetch Hetchy project are very different things.

Net horse-power to the amount of 115 000 can be developed from the ultimate 400 000 000 gal. per day supply, at a cost for power-house and machinery installation of $6 000 000. A large part of this power must be disposed of at cost. For the remainder, the Railroad Commission will fix the rates, at least, practically.

So much for the cost to the City. There is also a cost to society, as any water diverted out of the shed will, within 25 years at most, be needed locally for irrigation (400 000 000 gal. per day (445 000

acre-ft. per annum) is probably enough to irrigate 200 000 acres of citrus lands or 130 000 acres of valley land). Assume the cost of putting such water on the land at $125 per acre, the value of land with water at $500, and without water at $50. The value of water, therefore, would be $325 per acre, 25 years hence. Taking 175 000 acres, the total is $56 875 000, and the present value of this (interest at 4½%) is $18 924 000.

This must also be used with caution, because:

1.—It is doubtful whether the City can obtain 400 000 000 gal. per day from this source to divert.

2.—It is not certain that all the water to be diverted is really needed for local lands. The exact limits of the irrigable area east of the 300 000 acres of the Turlock and Modesto Irrigation Districts have not been definitely determined. Neither is it known how much, if any, of this can be otherwise watered, from other streams, or by pumped wells. Where this may be practicable, the cost to society is the increase in irrigation costs capitalized.

3.—There are no reliable data to determine how many acres the diverted water would irrigate, nor the cost per acre of applying it.

4.—The time in the future, when the lands would otherwise be intensively used, may not be the 25 years taken. It is certain that relatively little of the land would be properly watered immediately, because the irrigationists have not now the financial ability. It would undoubtedly be done in less than 25 years, however.

Relative to this, it is well to remember that ultimately water will be taken from the Sacramento River near its mouth and carried south to help irrigate the insufficiently watered San Joaquin Valley. When this is done, the water will doubtless be taken along the western edge of the valley, where the rainfall and run-off is only a fraction of that on the west slopes of the Sierra Nevadas. It is certain that for at least 50 miles south of the Tuolumne, as far as Kings River, no Sacramento River water will be brought across the San Joaquin Valley to supplement the Sierra Nevada streams in their respective tributary valley areas.

In any event, the present value of the cost to society of the City's selecting this supply is tremendous. This fact, more or less clearly understood, is the cause of much very bitter feeling in the Turlock and Modesto Districts. This bitterness accentuates the un-

fortunate, but in some measure justifiable, feeling common in the City's back country that San Francisco is self-centered and selfish.

Approximate Estimates.—Although there are these several elements of uncertainty, some estimates of the quantity of water which can be secured and of the cost are necessary for comparative purposes, if for nothing else. Assume that 1 500 000 acre-ft. of storage can be provided in about 40 reservoirs very well distributed over the water-shed, and that such a storage system can be operated with 80% over-all efficiency,* including evaporation during the frequent 2 to 2½-year storage periods. From the hydrograph of the Tuolumne River at La Grange, Fig. 22, it would appear that, for the 2½ years ending November 1st, 1913, the total safe draft would have been about 1 200 000 acre-ft. per annum, with all reservoirs empty at the end of the period. During the 29 months the Tuolumne River would be dry below La Grange. Another critical period would have occurred in 1897-99. Judging from the precipitation record beginning in 1868 at La Grange—which is not a satisfactory indicator of conditions, but about the only one available—similar critical periods occurred, ending, respectively, November 1st, 1878 and 1888. In other words, such cycles seem to occur about every 10 years, covering 23% of the time. The average cost of 1 500 000 acre-ft. storage capacity would probably be at least $30 per acre-ft.,† or a total of $45 000 000. Other interests might be induced to provide half of this, or incidental power might be secured which would cause an equivalent result. Consequently, the cost to San Francisco of such a quantity of storage may be taken at between $22 000 000 and $23 000 000. As the water requirements of the irrigation districts are so much larger than those of the City, and as the ultimate use will develop so much more quickly, the mean date of construction would probably be about 1930. This would make the present value of storage cost $11 620 000.

The construction cost of the initial installation, 1914-20, exclusive of the Tuolumne water-shed storage, for 160 000 000 gal. per day, would probably be about $55 000 000, according to the City's

* To secure such an efficiency it would be necessary to sacrifice most of the great power possibilities of the water-shed, because of different water requirements. For this reason, the City in 1912 asked the U. S. Forestry Service to permit no water storage in the Tuolumne drainage area above La Grange which the City would not control.

† More probably the average cost for such a quantity of storage would be more than $40 per acre-ft. capacity.

revised estimates. Using the consumption curves adopted by Mr. Wadsworth to secure comparative results, a second installation, increasing the capacity to 240 000 000 gal. per day, at an estimated cost of $11 000 000, exclusive of the Tuolumne storage, would be

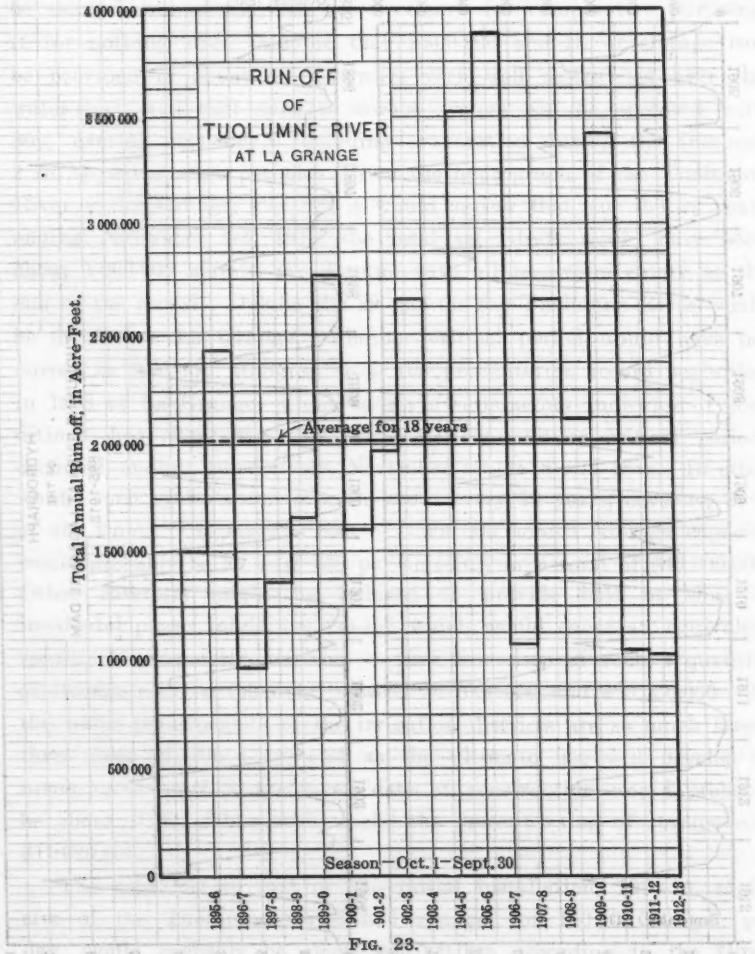

FIG. 23.

required at the mean date, 1946. A second installation, to increase the capacity to 400 000 000 gal. per day, at a mean date of 1966, will cost, exclusive of the Tuolumne storage, about $13 000 000. The present value of these expenditures is $51 650 000. Nothing is in-

cluded for renewals of short-lived materials, only initial costs. Plans which will make the Tuolumne River below La Grange dry for from 24 to 30 consecutive months, one-fifth of the time, will necessitate the acquisition of all riparian rights on the stream and many underground water rights in the region. The Wright Irrigation Law, under which the irrigation districts were formed, may have to be amended before any water can be taken out of the water-shed. The cost of necessary water rights may thus be considerable.

The value to the City of the ultimate quantity of incidental power which it has been proposed to develop can, under the conditions, be no more than $3 000 000, and the mean date about 1925. The value of power to society other than the City would probably be about an equal amount. With interest at 4½% the present value of the credit to the City is $1 848 000. Other power opportunities in the water-shed have been taken into consideration in estimating the cost to the City of storage required.

The present value of the project's cost to society, the value of the water for irrigation of lands east of the Turlock and Modesto Irrigation Districts, is, say, $17 500 000. There is a credit of, say, $3 000 000 for the proposed power installation, leaving society's net cost $15 652 000.

The grand total cost (present value) is $65 454 000.

Quantity of Water Obtainable.—The City will secure per annum whatever part of 1 200 000 acre-ft. is in excess of the irrigation needs of 300 000 acres. If such needs are 750 000 acre-ft., the City can obtain 450 000 acre-ft., or 400 000 000 gal. daily. If the irrigation needs are 900 000 acre-ft., the City can obtain 300 000 acre-ft. per annum, or 273 000 000 gal. daily, and if 1 050 000 acre-ft., then 150 000 000 acre-ft. per annum, or 136 000 000 gal. daily. The quantity available is chiefly a question of the irrigation needs of the 300 000 acres of land in question.

The writer believes that the ultimate irrigation duty of water for this land will nearly equal that in Imperial Valley, California. The two regions have much the same climate, both are essentially alfalfa and stock districts, with almost identical crop adaptations, and will doubtless have similar social conditions. The rainfall in the Turlock and Modesto Irrigation Districts averages about 9 in. and in

the Imperial Valley only 3 in., but in each case practically none occurs during the irrigation season. As an offset, the San Joaquin Valley lands are much more porous than those of Imperial Valley, which are the closest ever successfully irrigated on a large scale. All irrigation water in Imperial Valley is sold on a metered basis, and is used with care and economy. Indeed, practically no drainage system has ever yet been seriously suggested though the entire area is extraordinarily level. The irrigation canals are sealed with a deposition of fine Colorado River silt, so that the seepage loss of the distribution system is quite as low as could be expected from concrete-lined canals.* Imperial Water Co. No. 1 has 101 670 acres under actual cultivation in a compact body with the crops shown in Table 4.

TABLE 4.

Crop.	Number of acres.	Percentage.
Alfalfa	54 280	54.0
Alfalfa and barley	18 600	18.4
Barley	9 710	9.6
Corn	6 790	6.7
Cotton	6 150	6.0
Corn after barley	3 500	3.4
Melons	3 000	3.0
Miscellaneous	2 880	....
Alfalfa and corn	880	....
Vineyards	820	....

The net quantity of water actually delivered to the highest corner of each 160-acre tract of land during 1912 was 318 000 acre-ft., and in 1913, it was 325 000 acre-ft.

Safety.—As to relative safety, the presence of "active faults" in the Mt. Diablo Range, which will be crossed by the pressure tunnels, is a matter which many local engineers regard as very serious. Mr. Freeman holds the opposite opinion, and greatly prefers this construction to the Carquinez Straits crossing.

Quality of Water.—Water obtained from this source would be very soft (hardness about 20). All the contributory water-shed lies within the Yosemite National Park, and, therefore, will have no permanent population. On the other hand, with the improved transportation facilities to be made on the terms of the Raker Bill, the

*"Irrigation and River Control in the Colorado River Delta," *Transactions*, Am. Soc. C. E., Vol. LXXVI, pp. 1428-1431.

number of tourists, summer visitors, and campers on the water-shed will soon become a matter of importance. Taking this into consideration, together with the constantly rising standards in the quality of water supplies, Mr. Allen Hazen and Dr. Rupert Blue, Chief Surgeon, U. S. Navy Department, at the hearing before Secretary Fisher, in November, 1912, agreed in the opinion that complete filtration would be required in about 50 years, possibly sooner. Except for being softer, it would, under existing conditions, be almost exactly on a par with the water now delivered from Crystal Springs Reservoir. Judging from small reservoirs in the mountain regions, there is a possibility that greater trouble would be caused by minute organisms, such as algæ.

Possibility of Enlarging Supply.—If all the Bay communities pool their water supplies, distant supplies will probably not be required before 1945, and by 1990—taking the upper limit of 400 000 000 gal. per day as the quantity which may be obtained from this source—the combined sources will become inadequate within a period of 45 years from their introduction. Long before the latter date, it will be out of the question to secure any more supplies from that general region, and additional water will be obtainable only from the Sacramento River or some of its tributaries, that is, some of the northern sources, the construction of any one of which would be entirely independent of the Tuolumne works.

Combination of Sources.—Obviously, numerous combinations of the various Southern Sierra sources can be made, as well as of those of the Northern Sierras. Some of these may offer considerable advantages.

Conclusions.

Summarizing the salient features of the needlessly complexed political, sociological, and engineering problem, it appears to the writer that the citizens of San Francisco should take stock, and determine:

A.—Whether the water problem of San Francisco is primarily one for San Francisco alone or for Greater San Francisco-Oakland.

B.—Whether San Francisco should attempt to shoulder the financing and responsibility of an entire metropolitan district supply.

C.—Whether the present water system and sources supplying San Francisco proper, when owned actually by the City and properly improved and extended, are not satisfactory and adequate for the needs of the main City for the next two or three generations.

D.—Whether the other portions of Greater San Francisco-Oakland, and particularly the cities of Oakland, Berkeley, and Alameda, are not far more concerned than San Francisco in distant water supplies.

E.—Whether, on sentiment, San Francisco can afford to invest, in a new and distant water plant, sums so vast that many other requirements more vital to the interests of the City must be sacrificed or skimped.

F.—Whether the Hetch Hetchy scheme in its final form is a sound and practical one, from the engineering standpoint, and whether engineers of practical western experience, who are best qualified to pass on its peculiarly western problems, generally endorse or generally question it.

G.—Whether the Raker Act does not strip from the Hetch Hetchy project most of its advantages and assets, leaving the City in the position of "holding the bag" for others.

H.—Whether, all things considered, the only wise line of policy for San Francisco to follow is not:

First, to consummate the acquisition of the present water system, with all its appurtenances;

Thereafter, to take the water situation out of politics by having water matters handled by a Water Board of very wide powers, and entirely independent of all other City authorities;

Thereafter, to improve, extend, and amplify that system to meet fully all the City's needs for 70 or 80 years to come;

And, thereafter, to weigh carefully the relative advantages of entering into the vast Hetch Hetchy scheme or taking up some of the more important sociological problems, with a view to the more rapid and substantial development of the City itself, and let the other Bay cities work out their own water destiny for themselves.

Also, that the citizens of the East Bay cities should consider and decide, in addition to some of these same things, the following:

A.—Whether they should not acquire the existing water-works on the mainland, and at once improve, extend, and amplify them fully.

B.—Whether, as these cities are really in competition with Los Angeles rather than San Francisco, distant sources necessitating rates exceeding 15 cents per 1 000 gal. can be afforded.

ACKNOWLEDGMENTS.

The writer is indebted to many engineers and others for valuable suggestions and other assistance in preparing this paper. It is desired to extend grateful acknowledgment and appreciation to all of them. Especial thanks are due J. H. Dockweiler and C. E. Grunsky, Members, Am. Soc. C. E., particularly for the use of private reports and data.

THE LOCK 12 DEVELOPMENT OF THE ALABAMA POWER COMPANY, COOSA RIVER, ALABAMA.

BY E. L. SAYERS AND A. C. POLK, MEMBERS, AM. SOC. C. E.

TO BE PRESENTED NOVEMBER 4TH, 1914.

SYNOPSIS.

The object of this paper is to describe the design and construction of a low-head hydro-electric plant recently completed in Alabama, and thereby bring out a discussion, if possible, on the latest ideas in the practice of developing water-power under low heads, the latest features in hydraulic turbine design, modern methods of transmission, and the construction of such plants.

The Alabama Traction, Light, and Power Company was organized in 1912 for the purpose of developing the water-powers of Alabama. The Company acquired several public service companies operating steam generating plants, street railways, gas plants, etc., and several companies owning undeveloped water-power sites. Among the latter was the Alabama Power Company, which owns a site known as "Lock 12" on the Coosa River at a central point in the State.

This plant will form the hub of an extensive system of power

NOTE.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

plants capable of developing 24-hour, 80% efficiency power in excess of 500 000 h.p.

The foundations of the power-house are built transversely to the axis of the river and form an integral part of the dam. The length of spillway, power-house, and abutments, over all, is 1 530 ft. 5½ in. The power-house substructure is 303 ft. 4 in. long, 136 ft. 5 in. wide, and contains provision for six units. Four units constitute the present installation, and the superstructure is built with a temporary wall at the river end so that it can be extended to cover all six.

The spillway forming the principal part of the dam has a net crest length of 780 ft., divided into twenty-six sections, each 30 ft. long, separated by concrete piers, 6 ft. long on the axis of the dam. On the crest of each section of spillway there is placed between piers a gate, 30 ft. long and 14 ft. high, of a modified Stoney type. The height of the dam from the average elevation of the original river bed to the elevation of the flow line of the reservoir is 77 ft.

In all, there are approximately 190 000 cu. yd. of concrete in the power-house foundations and the dam. The first concrete was placed on April 12th, 1913; it was all placed by February 26th, 1914; and commercial power was turned out for the first time on April 12th, 1914, just one year, to the day, from the date of placing the first concrete.

The installation is made up of four vertical, single-runner turbines, guaranteed to deliver to the shaft, under 68 ft. head, at 100 rev. per min., 17 500 h.p. One feature of these units, as described in the paper, is that they are entirely self-contained, that is, they can be built up on an assembly floor from the foundation ring to the top of the direct-connected exciter above the generator, without requiring any lateral support.

Another feature of the development, as described in the paper, is the use of an improved volute casing, through which the water passes from the penstocks to the wheels. These scroll casings were complicated in form, and were moulded directly in the concrete of the power-house foundations, without the use of a steel lining.

After giving a brief description of the general system of the Alabama Traction, Light, and Power Company and of the power market to be served, the paper describes the Coosa River and the cli-

matic conditions under which the work was done, so that a better idea can be had by those not familiar with the locality.

The machinery is fully described, greater detail being given in the case of the turbines than for the electrical equipment, discussions of which are constantly appearing in papers of electrical societies and in the electrical technical press.

In connection with the construction of the plant, the materials used and their sources, the general scheme of handling the work and its prosecution, are dealt with in detail. The selection of plant, its layout, and the construction of camps are described, and improvements which experience showed could have been used, are noted.

The concrete forms used in the power-house foundations were necessarily complicated, and the details of their design and construction are shown. The various methods used in placing concrete and the success attending their use are described.

At the end of the paper, the design and construction of transmission lines and sub-stations are dealt with briefly.

Introductory.

In the last 10 years the progress made in methods of generating electric power and transmitting it over long distances to markets has been very marked, and although more or less complete descriptions of hydro-electric developments have been appearing in various technical papers, there has been no extended discussion of modern methods before this Society. This fact appears the more strange because at the present time a large amount of work is being done in developing the water-powers of the United States, and this branch of the Profession is fast becoming one of the most important.

No extraordinary features are claimed for the work described. The plant develops power under the moderate head of 68 ft., the installation of 70 000 h.p. is not remarkable, and no great difficulties in construction were met. It is believed, however, that it represents the latest improvements in equipment, and that a full discussion of this development and others of similar proportions will be of practical value to the Profession by bringing before it the latest practice in developing water-power under low heads, the latest features in hydraulic turbine design, modern methods of transmission

of high-potential current, and methods of construction which have been tried and found successful.

General System of the Alabama Traction, Light, and Power Company.

The Alabama Traction, Light, and Power Company, organized in 1912, acquired the properties, rights, and franchises of several public service companies in Alabama, and of several companies owning water-power sites in the State. Among the latter were the Alabama Power Company, with several undeveloped sites on the Coosa River; the Alabama Interstate Power Company, with a site on the Tallapoosa River; the Little River Power Company, with a site on Little River; and the Muscle Shoals Hydro-Electric Power Company, owning three sites on the Tennessee River. These sites represent a possible development in excess of 500 000 h.p. continuous 24-hour power.

The developments proposed by the Company on the Coosa are at the sites selected by the United States Government engineers for dams and locks for the improvement of the river. Fig. 1 is a profile of the Coosa River covering that portion affected by the proposed developments. The dam farthest south, at which power could be developed, is at a point 7½ miles above Wetumpka. This site, known as Lock 18, has an effective head of 63 ft., and the dam would raise the water to Elevation 254 (U. S. Army datum) from Elevation 190. At Lock 15, the next site, 19½ miles above Wetumpka, the water would be raised from Elevation 254 to Elevation 294, giving an effective head of about 39 ft. At a point about 34 miles above Wetumpka, the dam at Lock 14 would raise the water to Elevation 352, giving an effective head of about 57 ft. Lock 12 is 40 miles above Wetumpka, and here the water level is raised to Elevation 420, making the effective head of 67 ft. These sites are all shown on the general map, Fig. 2.

The proposed development on the Tallapoosa River is at Cherokee Bluffs, about 30 miles northeast of Montgomery. Here a dam 180 ft. high would back the water up 30 miles in the river, making one of the largest storage reservoirs in the country, the area being 34 000 acres.

The Little River development is in the northeastern part of the State (see Fig. 2), about 33 miles northeast of Gadsden. The devel-

opment at this point would consist of a storage reservoir on Little River, a tunnel through the mountain, and a pipe line to a power-house in the valley below.

The developments on the Tennessee River are at Muscle Shoals, a short distance above Florence. Two plans for the development of the water-power in connection with the improvement of the river have been proposed, one involving two dams and the other three, each scheme, however, would accomplish the same result.

Possible Combination of Developments.—The Government engineers have proposed the construction of a large storage reservoir on the Etowah River, at the head-waters of the Coosa River, for the purpose of regulating the flow of both the Coosa and Alabama Rivers, in the interests of navigation. The construction of this reservoir would obviously be of great advantage to the developments on the Coosa River, because the low-water flow would be increased to 4 700 sec-ft.

Considering the Coosa River projects as a connected system, tying together Lock 12, Lock 18, and the intermediate developments, and using the storage of the Etowah Reservoir, there would be produced in the dryest year 143 000 of continuous, 24-hour, 80% efficiency, horse-power, and, in an average year, 268 000.

The Cherokee Bluffs Reservoir, as proposed, will have an area of 34 000 acres, and the available storage will be 50 000 000 000 cu. ft. Using this in connection with the Muscle Shoals and Little River developments, and taking advantage of its great storage in times of low water on the Tennessee, the continuous 24-hour, 80% efficiency, horse-power in dry years would be 334 000, and in an average year 505 000.

By combining these two systems, it will be seen that, in the ultimate development, there is obtainable 24-hour, 80% efficiency, to an amount in excess of 550 000 h.p., with a 100% load factor. On the ordinary commercial load factor there would be required a capacity of about 1 000 000 h.p., which is probably in excess of the amount that the State will use for many years to come.

A knowledge of these facts is only desirable in that they partly explain the reasons for the adoption of certain types of construction as being part of an extensive proposed system.

DISTRIBUTING SYSTEM
OF THE
ALABAMA POWER COMPANY

FIG. 2.

On Fig. 2 is shown the primary transmission system proposed to connect ultimately the developments at Cherokee Bluffs, Lock 18, and Muscle Shoals, with Lock 12 and with the principal industrial centers of the State. As at present constructed, the system uses power developed at Lock 12, at a steam turbo-generating station at Gadsden, and at a small hydro-electric plant at Jackson Shoals. The cities to which power is now being served are indicated by the solid lines.

Power Market.—With regard to the power market, Alabama at present may be considered as divided into two distinct sections. In the northern half are the coal and ore mines, several cement mills, and all the industries usually found in a mineral section. Birmingham is in this section, its rapid growth being due mostly to the mineral resources of the Birmingham District. Great development is going on there, the present demand for power being greater than in the rest of the State, and there is little doubt that this demand will increase tremendously in the years to come. In the southern half of the State are the cotton-growing districts and the shipping centers along the Gulf of Mexico. Aside from street railways and electric lighting, the power consuming industries of the southern section are limited almost entirely to cotton mills. For this reason, it would be necessary, in order to market the immense quantity of power from Cherokee Bluffs and the Lock 18 developments, to introduce new industries, preferably those dependent on a large supply of cheap power, such as the manufacture of fertilizers of the variety using the fixation of atmospheric nitrogen.

In Table 1 is given the population of the principal cities of Alabama, showing their growth between 1890 and 1910.

Initial Development.—In July, 1912, it was decided that the initial development of the Company should be at Lock 12 on the Coosa River, rather than at Cherokee Bluffs on the Tallapoosa. This decision was based on a number of considerations, principal among which was the fact that in the Government grant of the Lock 12 site the right to develop power was contingent on the completion of the construction of the dam at this point on March 4th, 1914. If construction had not been prosecuted promptly at this site, a grant of great value to the Company would have been lost. The requisite funds for the initial development had been raised, and each day's

*In 1909 Birmingham absorbed a number of adjoining towns into the "Greater Birmingham." This accounts for the great increase in population; the rate of increase, however, is remarkably large, the population in 1914 being reported unofficially as 166 000.

delay was costing a large sum of money, and furthermore, it would have been impossible, on account of certain legal difficulties, to start construction at Cherokee Bluffs for a number of months. Besides these facts, the original outlay for the Cherokee Bluffs development was estimated to be more than 50% greater, and the cost per installed horse-power somewhat more, than at Lock 12.

A description of the Coosa River, and of the climatic conditions prevailing in the district, will be given, and, as a large proportion of the membership of this Society is resident in and about New York City, comparisons are made with conditions prevailing in that vicinity.

Coosa River.—The Coosa River, which constitutes part of the drainage system of the Mobile Basin, is formed near Rome, Ga., by the confluence of the Etowah and Oostanaula, which have their sources in the mountains of Northwestern Georgia.

The river flows in a general westerly direction over the Piedmont Plateau from Rome into the State of Alabama, where it turns in a southwesterly direction and meanders through wide valleys to Gads-

den. Here, again, the river changes its general trend, turning more toward the south and flowing in a more direct line, between mountains of limestone formations. A short distance below the crossing of the Louisville and Nashville Railroad about opposite Sylacauga, the river passes out of the limestone formations into the slates and schists, and the bed of the stream becomes hard and very rough. From this point the river flows in a southeasterly direction over a succession of shoals and riffles to Wetumpka, where it joins the Tallapoosa River to form the Alabama. In this last section, where the fall in the river is more abrupt, a large quantity of power can be developed economically.

The first project for improving the river for navigation was proposed in 1875, and some work has been done in the general scheme of making the river navigable for light-draft boats. The system, when completed, will be a waterway, almost 900 miles long, from the head-waters of the Coosa to the Gulf of Mexico. Prior to 1912, however, no improvements had been made in the rough section of the river between Gadsden and Wetumpka.

In its upper reaches the Coosa flows through clay-covered territory where it accumulates from its feeders, in all except extreme low-water seasons, a quantity of silt, making it appear very muddy. Tests, however, have shown that this extremely muddy appearance is due in great part to material which has gone into solution in the water, as at its worst it carries in suspension not more than 1 part of silt in 6 000. It is not anticipated, therefore, that there will be any considerable difficulty from silting of reservoirs on this river.

The source of the river is in a region which has a heavier annual rainfall than any section of the United States, with the exception of some parts of the State of Washington. The surface rocks are mostly limestones, which, of course, are only moderately porous; but they are broken up with large fissures, and the solvent action of the rainfall has converted many of these fissures into subterranean channels, as shown by the number of large springs which abound in this territory. To a certain extent, this condition, has a regulating effect on the watercourses emptying into the Coosa, yet in the winter and early spring of the normal year the rains are intense, and the river is subject to floods from December until April, with occasional flashy floods before and after that period, the month of greatest flow being March. The regulating effect of these springs and the fact that in

the average year the rainfall is distributed somewhat uniformly over the months are responsible for the fact that the low-water flow of the Coosa is ordinarily nearly three times as great as that of the Hudson at Albany, and is equal to the low-water discharge of the Mississippi at St. Paul. Table 2 gives the discharge record of the river from 1897 to 1914, inclusive.

The greatest flood known in the river occurred in the spring of 1886, before gauge readings had been commenced. At Lock 12 this flood has been variously estimated, by engineers who have studied and reported on the Coosa River projects, to have been from 95 000 to 170 000 sec-ft. Extensive studies made during 1913 have indicated that the probable flood intensity was approximately 135 000 sec-ft. The average spring flood in the last 14 years, during which time observations have been taken continuously has amounted to 80 000 sec-ft.

The area of the water-shed above Lock 12 is 9 087 sq. miles. Using the estimated maximum flood of 1886, 135 000 sec-ft., this would give a maximum discharge of 14.8 sec-ft. per sq. mile of water-shed, which is one of the smallest in the country. This is explained principally by the fact that the water-shed is very large, and the average intensity of rainfall during a storm is very small. To illustrate this, a few examples of flood discharges are given in Table 3.

The lowest flow known to have occurred was in 1904, at which time observations were taken at Riverside, 72 miles above Lock 12. A comparison of the gauges and rating curves at these two points indicates that the minimum flow was 1 700 sec-ft. at Lock 12. The average minimum flow since observations have been taken amounts to 5 000 sec-ft. With the regulation effected by the construction of the dam at Lock 12, the minimum flow of 1904 would have amounted to 2 400 sec-ft.

Climatic Conditions.—Few people in the North realize that Birmingham, Ala., has had a greater range of temperature, both at the upper and lower limits, than New York City. The records of the United States Weather Bureau show that the maximum temperature of New York City is 100° and that the minimum is — 6°, and that the temperature has ranged between 104 and — 10° at Birmingham.

In summer the heat is intense, but of an entirely different character from that of New York City. For long periods the temperature during the day ranges between 90° and 100°, but heat prostrations

long duration. Ice is never formed to any thickness in ponds or rivers, and the mid-day sun almost invariably causes the temperature of the coldest days to rise above freezing.

It is not necessary, therefore, to consider the effect of an ice thrust in the design of a dam in this climate, and, for the same reason, no precaution need be taken in the design of forebays, for the care and handling of ice at penstock screens. Needless to say, no difficulties are encountered with frazil.

To make clearer the rainfall conditions, Table 4 shows a comparison between the records of normal monthly precipitation at New York City and at Birmingham. From this it will be seen that the rainfall in New York City is more evenly distributed throughout the year than in Birmingham, and that, from December to March, inclusive, the Birmingham rainfall is far in excess of the mean monthly. In July and August, the precipitation at each place is about equal and is the result of heavy showers of short duration.

In the normal year, construction work in Alabama is hampered to a large extent in winter by rains of several days' duration. At such times it is impossible to carry on work, because laborers, even if provided with suitable clothing, will not turn out.

Work Done to Date.—In April, 1912, E. A. Yates, Assoc. M. Am. Soc. C. E., was appointed Chief Engineer of the Company, and an en-

gineering and construction force was organized. A party was put in the field at Cherokee Bluffs for the purpose of surveying the flooded area (34 000 acres) of that reservoir. A short time later an additional party was placed in this reservoir, and a large party was put to work on the surveys for the Coosa River reservoirs. The surveys for the Muscle Shoals reservoirs were made in 1913.

At the time the decision had been reached that the initial development should be at Lock 12, no plans of the development had been drawn up, with the exception of a general plan and elevation of the proposed structure. Only 1½ years remained for the construction of the dam within the time stipulated in the Government grant, and, therefore, it was impossible to draw up complete plans before proceeding with the construction. It was desirable to let a contract for the construction of the power-house foundations and dam to a contractor having plant and equipment ready to be moved to the work without delay. Such a contract was let, for the construction of the power-house foundations and dam, on a cost-plus-fixed-fee basis, and the direction of the work, approval of selection of plant, and methods of attack were reserved to the Chief Engineer of the Company. It was decided that the construction of the superstructure and the equipment of the power-house should be done by the Company's own force. As soon as this contract was signed, the necessary preparations for starting construction were inaugurated.

An old lumber railroad (shown on Fig. 3), extended through the hills from a point where it had physical connection with the Louisville and Nashville Railroad, about 5 miles south of Calera, to a point about 5 miles from the dam site. It was known as the Clear Creek Railroad. It was not ideal for construction purposes, because, in its length of 18 miles, it had forty-two timber trestles, one switch-back, and many sharp curves, the sharpest being 35° on a 2.5% grade. The shortest, alternate line, however, would have been at least 14 miles long, and would have involved construction from beginning to end, with a large amount of heavy work. It was necessary to transport the heavy plant to the dam site at the earliest possible moment, and time was not available for the construction of such a line,

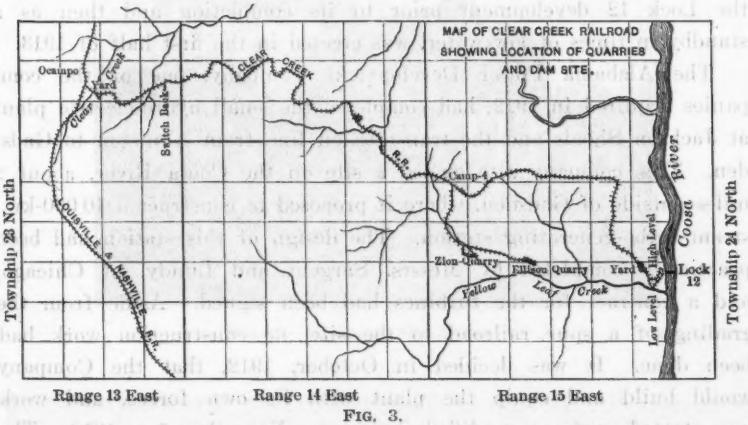

FIG. 3.

although the cost of the railroad as a unit would undoubtedly have been less. The construction and repair work on this railroad was started on August 12th, 1912, by the Company's forces, and on November 26th, the first car loads of the contractor's heavy plant were delivered at the dam site, at least 2 months earlier than would have been possible if an entirely new road had been built. Before this time, however, camps had been constructed at the dam, and preparations were being made for the installation of the plant. During the period when the plant was being set up, a coffer-dam, enclosing the area to be excavated for the power-house and a portion of the spillway, was constructed. This coffer-dam was unwatered for the first time on December 13th, 1912, and the excavation of the river bed was started.

Long delays occurred, due to heavy rains and floods, and it was not until April 12th that the first concrete was placed. In November, 1913, the power-house foundations having been prepared, the building of the superstructure and the installation of machinery were begun. All the concrete work of the power-house foundations and dam was completed on February 26th, 1914, 6 days before the limiting date set by the Government grant. The installation of the first unit was completed on March 22d, 1914. The completion of the installation of the other units followed within a short time thereafter. The first unit was tested out and dried and was put into commercial operation on April 12th, 1914, just 1 year after the first concrete was poured.

An auxiliary steam plant, to be used in building up a load for the Lock 12 development prior to its completion and then as a standby in times of low water, was erected in the first half of 1913.

The Alabama Power Development Company, one of the companies acquired in 1912, had completed the small hydro-electric plant at Jackson Shoals and the transmission line from Anniston to Gadsden. This company also owned a site on the Coosa River, about 2 miles outside of Gadsden, where it proposed to construct a 10 000-kw., steam turbo-generating station. The design of this station had been practically completed by Messrs. Sargent and Lundy, of Chicago, and a contract for the turbines had been signed. Aside from the grading of a spur railroad to the site, no construction work had been done. It was decided in October, 1912, that the Company would build and equip the plant with its own forces, and work was started under a modified design on November 1st, 1912. The plant was completed in June, 1913, but a delay in the delivery of the transformers prevented commercial delivery of power until July. Fig. 4 shows the exterior of the plant and Fig. 6 shows a section through the boiler and turbine rooms.

The construction of transmission lines and sub-stations was carried on simultaneously with the other work. The surveys for proposed transmission lines were started with three parties in July, 1912, the purchasing of right of way was begun in October, and actual construction was commenced in November. In March, 1914, the lines from Lock 12 to Birmingham (46.5 miles), from Lock 12 to Anniston, *via* Jackson Shoals (47.8 miles), from Sylacauga to Alexander City (25.1 miles), from Jackson Shoals to Leeds (26.5

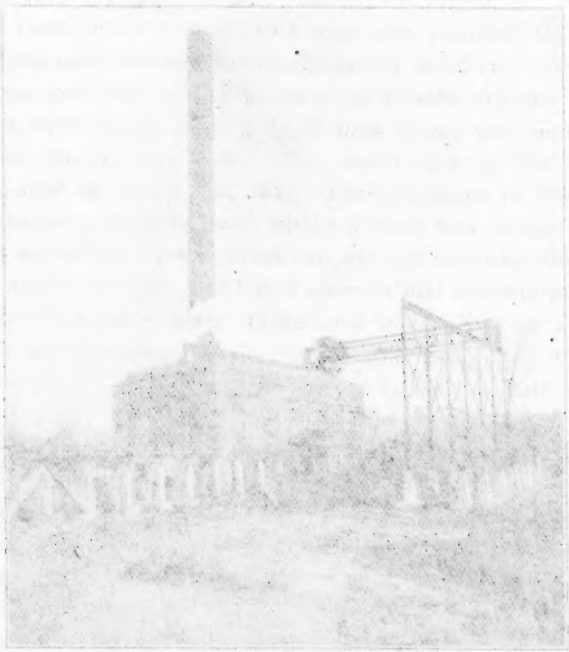

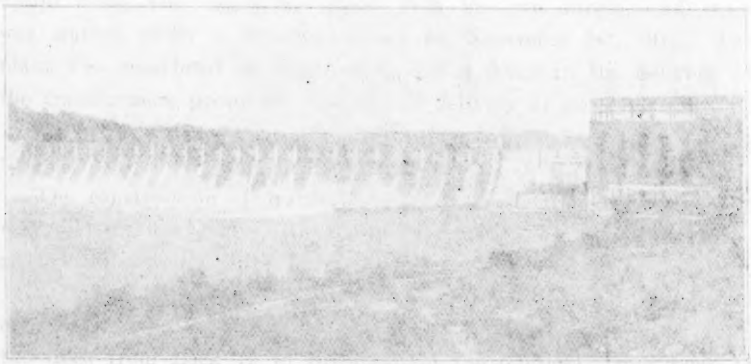

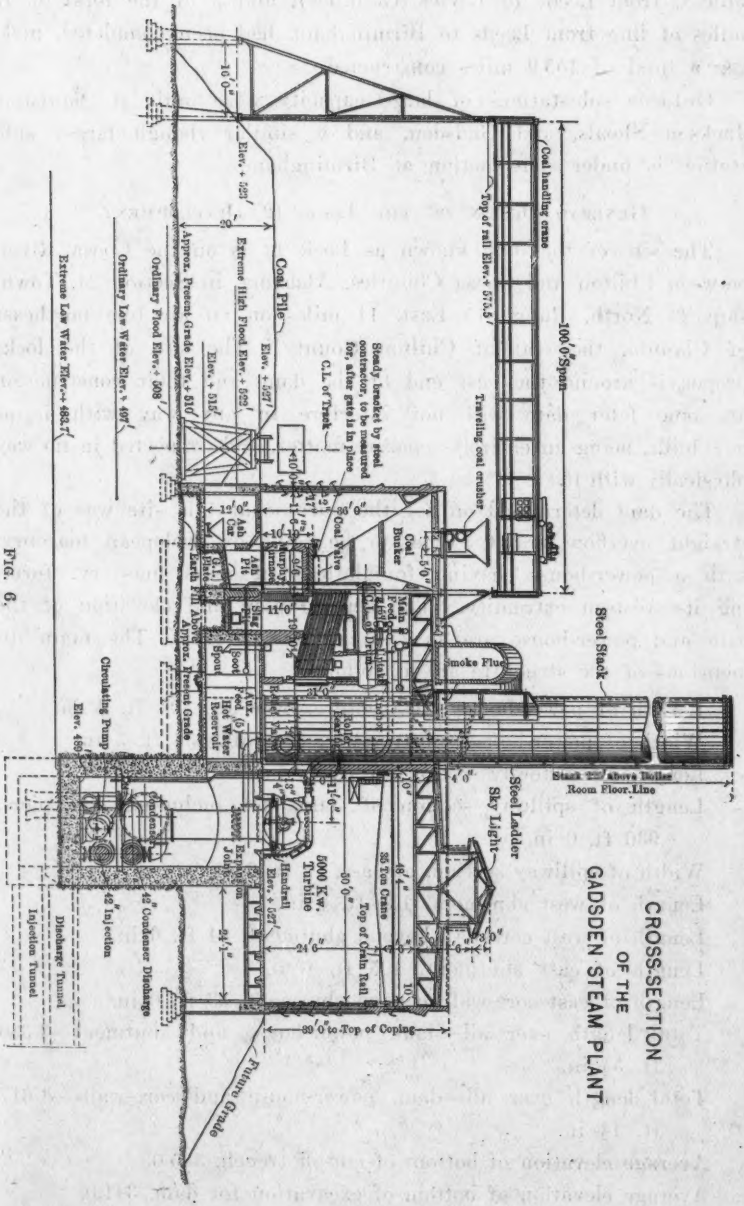

FIG. 6.—CROSS-SECTION OF THE GADSDEN STEAM PLANT

miles), from Leeds to Lovick (5 miles), and 5 of the total of 19 miles of line from Leeds to Birmingham, had been completed, making a total of 155.9 miles constructed.

Outdoor sub-stations of large capacity were built at Anniston, Jackson Shoals, and Gadsden, and a similar though larger sub-station is under construction at Birmingham.

General Design of the Lock 12 Development.

The site of the dam known as Lock 12 is on the Coosa River, between Chilton and Coosa Counties, Alabama, in Section 24, Township 23 North, Range 15 East, 11 miles on an air line northeast of Clanton, the seat of Chilton County. The site of the locks proper is around the east end of the dam, and their construction at some later date will not interfere in any way with it as now built, being an entirely separate matter, and connected in no way physically with it.

The dam determined on for the purpose at this site was of the straight overflow gravity type, to be built of cyclopean masonry, with a power-house, having foundations of mass masonry, forming its western extremity. The general plan and elevation of the dam and power-house are shown on Plate XXIII. The main dimensions of the structure are as follows:

Length of power-house substructure, over all, 303 ft. 4 in.
Width of power-house substructure, over all, 136 ft. 5 in.
Length of wasteway section, 57 ft. 1½ in.
Length of spillway section of dam, not including end piers, 930 ft. 0 in.
Width of spillway section, at base, 72 ft. 0 in.
Length of west abutment, 134 ft. 6 in.
Length of west core-wall beyond abutment, 34 ft. 6 in.
Length of east abutment, 105 ft. 6 in.
Length of east core-wall, beyond abutment, 53 ft. 0 in.
Total length over all—dam, power-house and abutment—1 530 ft. 5½ in.
Total length over all—dam, power-house and core-walls—1 617 ft. 1½ in.
Average elevation of bottom of cut-off trench, 335.0.
Average elevation of bottom of excavation for dam, 341.0.

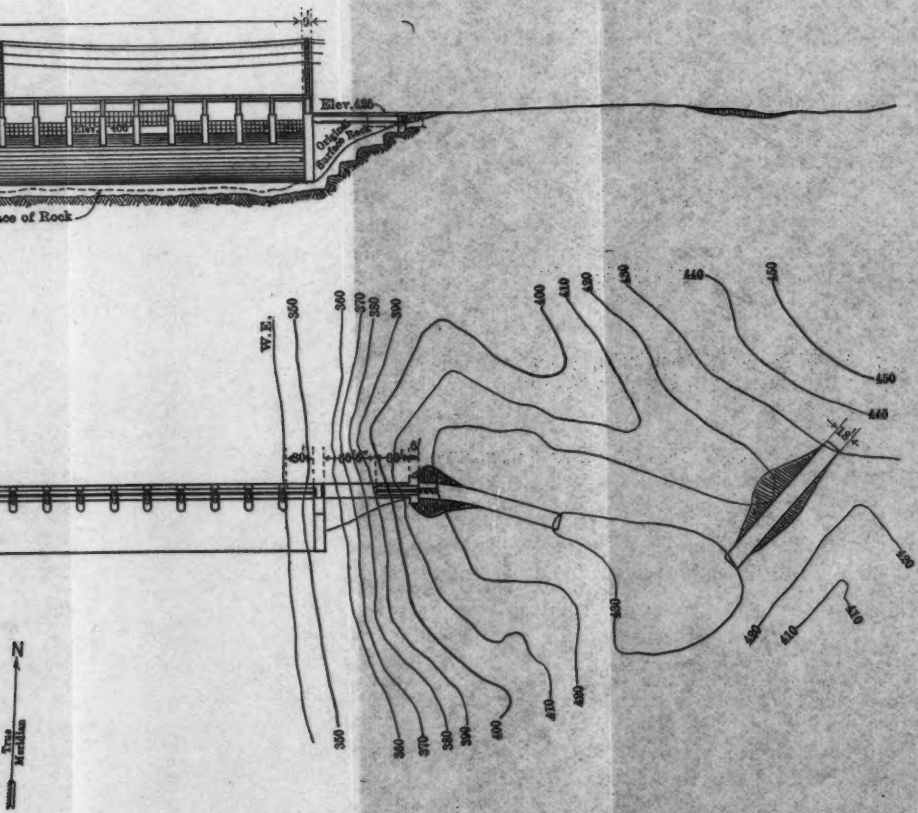
GENERAL PLAN AND ELEVATION OF LOCK 12 DEVELOPMENT

PLATE XXIII.
PAPERS, AM. SOC. C. E.
SEPTEMBER, 1914.
SAYERS AND POLK ON
HYDRO-ELECTRIC POWER DEVELOPMENT
IN ALABAMA.



Average elevation of bottom of river before excavation for dam, 343.0.

Elevation of crest of dam, 406.0.

Elevation of top of spillway piers, 444.0.

The spillway, forming practically all of the dam east of the power-house, has a net crest length of 780 ft., divided into 26 sections, each 30 ft. long, which are separated by piers 6 ft. long on the axis of the dam, the piers serving to carry flood-gates of the modified Stoney type.

At a point 11½ miles above Lock 12, the Louisville and Nashville Railroad crosses the Coosa on a through bridge of several trusses, and Peckerwood Creek, a tributary stream, immediately above this point, on a through plate-girder bridge. The elevation of the low steel on the truss bridge is 425.3 and of the plate girders 423.5. These elevations, allowing for the back-water effect which is exaggerated to some extent during floods by the Narrows (shown on Plate XXIV) about 5 miles below the dam, fix the normal elevation of the pond at 420, as established by the U. S. Army Engineers.

For the purpose of maintaining the normal pond level during floods, twenty-six flood-gates, each 14 ft. high, were designed to be placed on the crest of the spillway at Elevation 406. The abutment sections of the dam and the section between the power-house and the spillway in which are the wasteway culverts, are carried to Elevation 425, with parapet walls to Elevation 429.5.

The power-house is shown in cross-section by Fig. 7, on which it should be noted that the foundations are of mass concrete, the penstocks, scroll casings, and draft-tubes being moulded directly in the concrete with no lining of any kind.

One feature of this development, which is a decided improvement over most of those heretofore constructed, is that the units are entirely self-contained, that is, the turbine, generator, and exciter are self-supporting, and can be built complete, from the base ring of the turbine to the top of the direct-connected exciter, without requiring any lateral support from the concrete about the turbine casing during construction.

There are four units in the power-house, and provision in the foundations for two more. Each of the units has a capacity of

17 500 h.p. delivered to the shaft at a speed of 100 rev. per min., and under a head of 68 ft.

The adoption of this size of installation was dependent on many factors and a number of assumptions, a detailed statement of which is impossible here. It might be well, however, to note that the principal considerations involved were the ordinary working head, the reduction of head at times of flood, the nature and extent of the power market on which the load factor depends, the available steam auxiliary plants, and the relation of the plant at Lock 12 to the other proposed developments of the Company.

As noted previously, the year of lowest flow on record was 1904, when the discharge of the Coosa at Lock 12 dropped to 1 700 sec-ft. The storage of the reservoir, using a 10-ft. draw-down, increases the available draft to 2 300 sec-ft., which, with a 68-ft. head, will produce 14 200 h.p., of continuous, 24-hour power, having 80% efficiency. Combining this with the daily output of a steam plant with a capacity of 15 000 kw., there would be produced 614 000 kw-hr. per day, which, on a 50% load factor, is equal to 51 000 kw. maximum demand. A study of the horse-power percentage of time curve for Lock 12 shows that 70 000 h.p. on a 50% load factor, which is equal to 35 000 h.p., continuous, is available at Lock 12 for 80% of the time under a head of 68 ft. and 85% of the time under a head of 74 ft.

It should be noted that this is a pioneer development in Alabama, and that the character of the market is not as well defined as it is in most States where development has been going on for years. It was not known whether part of the load would be electro-chemical, or not, and it was necessary to assume the load factor on the best information obtainable from a hurried survey of the market.

It is estimated that the construction of the Etowah Reservoir at the head-waters of the Coosa, as previously mentioned, will increase the low-water flow of the river to 4 700 sec-ft. Assuming that Lock 12 would be operated ultimately in connection with this storage reservoir and the developments lower down the river, an ultimate installation of 105 000 h.p. is provided for in the power-house foundations.

FIG. 7.

Dam.—Fig. 8 shows the cross-section of both the spillway and the retaining sections of the dam. The assumptions of loading made in the design were as follows:

A maximum depth of water on the crest of the spillway of 19 ft., which is equivalent to a flood of approximately 200 000 sec-ft.;

An elevation of the water, back of the retaining section, of 425 ft., or 5 ft. above the normal lake level;

An upward pressure on the base of the dam varying in intensity from two-thirds of the head at the up-stream face to zero at the toe;

Weights of masonry and of cyclopean stone were assumed at 150 and 160 lb. per cu. ft., respectively;

As previously noted, it was not necessary to allow for any thrust from ice pressure.

The line of pressure developed under these assumptions is shown on the cross-sections. The assumption of an upward pressure of two-thirds at the head of the up-stream face, decreasing to zero at the toe, is probably too severe, in view of the fact that, although the foundation was slate rock, it was quite tight, and the dip of the strata was extremely favorable. However, the fact that this dam will unquestionably be called on to pass floods of 14 ft. over the crest, with the attendant vibration, and the fact that Montgomery, a large part of which is built on low ground, is only 40 miles down the river, made it imperative to use extreme assumptions on the side of conservatism.

Fig. 9 shows the cross-section of the spillway at Lock 12 superimposed on the cross-sections of the La Grange and Big Bend Dams. The former is reported to have passed floods of 15 ft. on the crest, and the latter was designed for floods of 20 ft.

Power-House.—Fig. 7 shows a cross-section of the power-house. The foundations throughout were of mass concrete, reinforced with steel rods around the penstocks, scroll casings, and over the draft-tubes. The computation of the stresses in such a structure is very complicated, as not only the ordinary provisions of dam design must be given attention, but the stresses transmitted from one part of the structure to another must be carefully investigated. open spaces within the structure permit of only approximate solutions, and ample safety factors must be allowed to cover the uncertainties. In determining the stability of the structure, the same assumptions as to loading were made as in the case of the retaining section of the dam. No allowance was made for the added

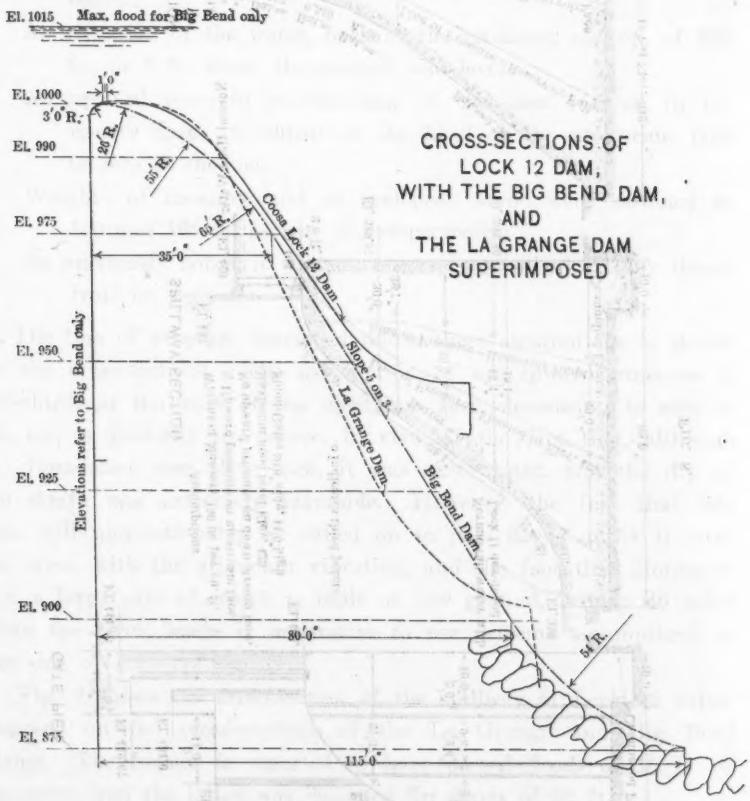

FIG. 9.

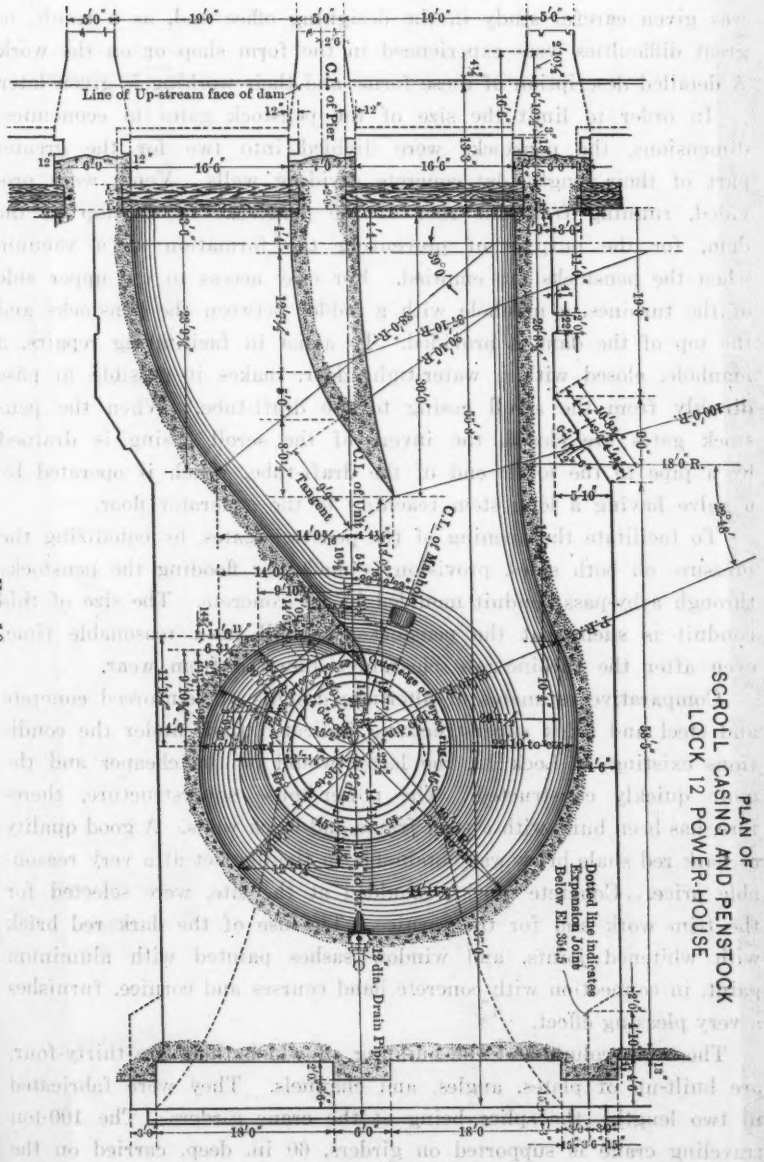
stability furnished by the weight of the superstructure and equipment, that is, the foundations were designed to be stable under full water pressure when bare.

As very little experience had been had with wheel casings of the volute or scroll type (see Plate XXV and Fig. 10), it was anticipated that there would be considerable difficulty in moulding them



PLAN OF SCROLL CASING AND PENSTOCK LOCK 12 POWER-HOUSE

FIG. 10.

directly in the concrete. For this reason, the structure of the forms was given careful study in the designing office and, as a result, no great difficulties were experienced in the form shop or on the work. A detailed description of these forms and their working is given later.

In order to limit the size of the penstock gates to economical dimensions, the penstocks were divided into two for the greater part of their lengths by concrete dividing walls. Vents were provided, running from the roof of the penstocks to the top of the dam, for the purpose of preventing the formation of a vacuum when the penstocks are emptied. For easy access to the upper side of the turbines, a manhole with a ladder between the penstocks and the top of the dam is provided. To assist in facilitating repairs, a manhole, closed with a water-tight door, makes it possible to pass directly from the scroll casing to the draft-tube. When the penstock gates are closed, the invert of the scroll casing is drained by a pipe to the lower end of the draft-tube, which is operated by a valve having a long stem reaching to the generator floor.

To facilitate the opening of the penstock gates, by equalizing the pressure on both sides, provision is made for flooding the penstocks through a by-pass conduit moulded in the concrete. The size of this conduit is such that the penstocks will fill in a reasonable time, even after the turbine-gate clearances increase from wear.

Comparative estimates of alternate designs of reinforced concrete and steel and brick superstructures indicated that, under the conditions existing at Lock 12, the latter would be the cheaper and the more quickly constructed. The power-house superstructure, therefore, has been built with a steel frame and brick walls. A good quality of dark red shale brick was obtainable in the district at a very reasonable price. Concrete blocks, moulded at the site, were selected for the trim work and for the cornice. The use of the dark red brick with whitened joints, and window sashes painted with aluminum paint, in connection with concrete band courses and cornice, furnishes a very pleasing effect.

The main columns of the building, of which there are thirty-four, are built-up of plates, angles, and channels. They were fabricated in two lengths, the splice being at the crane girders. The 100-ton traveling crane is supported on girders, 60 in. deep, carried on the main columns of the building. The roof trusses have a clear span

HOUSE

of 69 ft., are 9 ft. deep at the mid-point, and, in addition to supporting themselves and the dead load of the roof, are designed to carry, attached to their lower chords, the high-tension bus structure of the power-house, and, on top of the roof, the electrolytic lightning arresters and several outgoing line towers.

The floors of the power-house superstructure are of reinforced concrete slabs supported on steel beams.

Turbines.—The turbines selected for this installation are the largest capacity, vertical, single-runner turbines ever installed in the United States, to operate under a head of approximately 70 ft.

Fig. 11 is a cross-section through a complete unit, and Figs. 12 and 13 show the runner and the pit liner, respectively. The weight of a runner and shaft complete is 103 000 lb., and the weight of a complete turbine is 520 000 lb.

As previously mentioned, one feature in which these turbines differ from most of those heretofore installed is that they are self-contained. The bottom of the pit liner rests directly on the concrete foundation at the scroll-casing level, where anchorages make it possible to adjust the level of any point on it. This arrangement makes it possible to set up the turbine complete in the shop and do all the necessary machine work there, eliminating the very expensive machine work commonly done in the field. The installation of the turbine on its permanent foundation then becomes a comparatively simple matter, involving only the accurate setting of the base ring on the anchorages and the bolting up of the other sections of the pit liner to this ring. If the machine work in the shop has been accurate, the assembly in the field must be simple. The runner of these units is of cast iron and of the Francis inflow type, cast in one piece. The diameter of the runner, over all, is 13 ft. 3 in., and it is 7 ft. 2 in. high.

The casing or pit liner is made up of three rings; a heavy cast-iron ring, in two sections, forms a foundation for the rings above and transmits the weight of the generator and moving parts from them to the concrete foundation; it also serves the purpose of guiding the water from the scroll casing to the movable guide-vanes. This ring of the pit liner is commonly called the speed ring.

Above the speed ring is the intermediate ring. This serves to transmit the load to the speed ring, to form a water-proof lining for the operating chamber over the runner, and to carry the two gate-

operating engines of the turbine. Above this is the third section of the pit liner, the foundation ring, which rises to the elevation of the main floor of the power-house. On this ring is set the generator armature or stator, and the weight of the latter and of all moving parts is transmitted through it. Bolted to this ring, and forming part of it, is

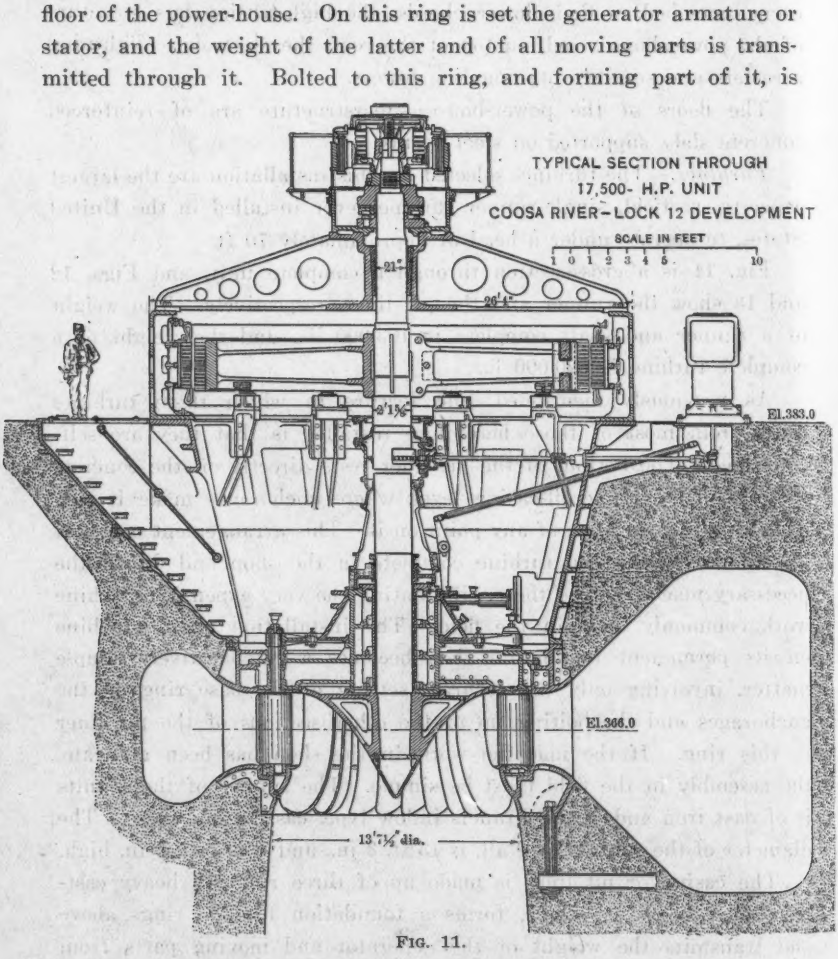

FIG. 11.

the cast-iron stairway giving entry from the generator floor to the operating chamber. The floor of the operating chamber is the cover-head, which is between the speed ring and the intermediate ring of the pit liner.

The shaft, 24 in. in diameter, is one solid piece, passing throughout the turbine, generator, and exciter. The weight of the shaft

FIG. 12.—RUNNER OF LOCK NO. 12 TURBINES IN SHOP.

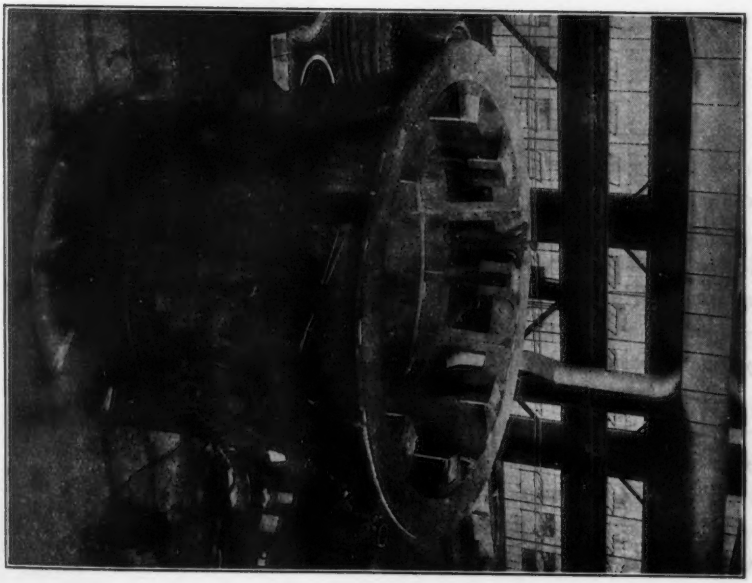

FIG. 13.—COMPLETE PIT LINER OF TURBINE ASSEMBLED IN SHOP.

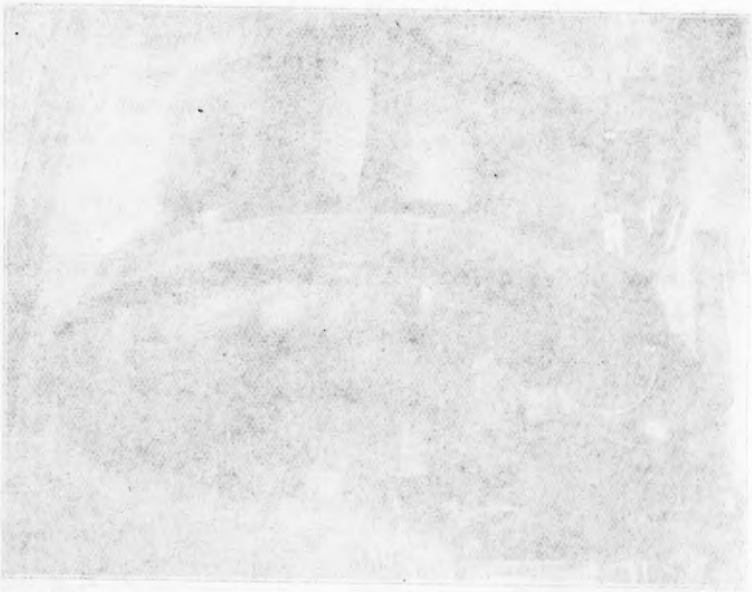

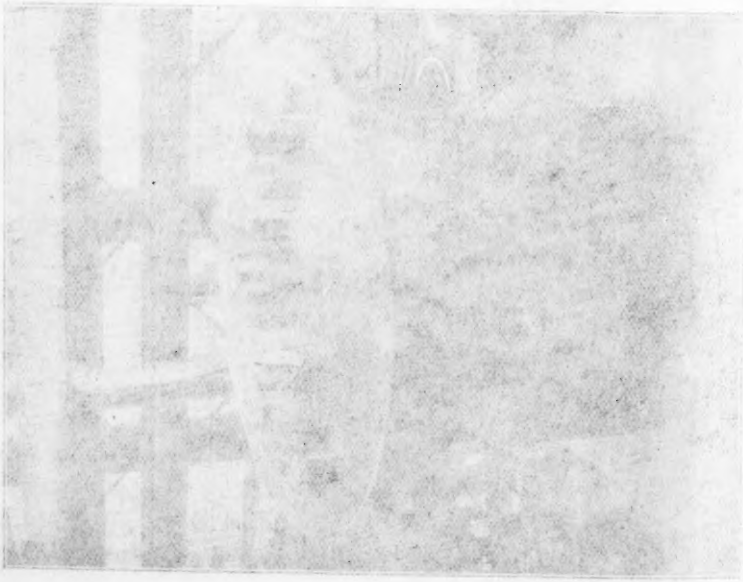

and the running parts attached to it is transmitted through a thrust-bearing, immediately above the generator and below the exciter, to the bridge on the generator. The runner is made a taper fit on the shaft, the torsion being taken on a long vertical key. A circular key and a cast-iron cap hold the runner in place. The shaft is held in position above the runner by lignum-vitæ guide-bearings in the cover-head of the turbine and by a Babbitted steady bearing under the bridge of the generator. The former is lubricated with water, and the latter with oil. The length of contact of the lignum-vitæ guide-bearings is 70¼ in.

The turbines in the plant are guaranteed by the manufacturers to deliver at the shaft 17 500 h.p., with a head of 68 ft. and a speed of 100 rev. per min.

The runner selected was stepped up from a model which, on a Holyoke test, developed a maximum efficiency of 89.68%, and the manufacturers have guaranteed that the units as installed will have a maximum efficiency of 87% when delivering to the shaft from 15 000 to 17 000 h.p. The efficiencies guaranteed at full and part gate are as follows:

Power.	Efficiency.
17 500 h.p.....	83 per cent.
15 300 "	85½ "
13 125 "	83 "
8 750 "	74 "

The efficiencies obtained in the Holyoke tests are higher than have ever been attained on any turbine heretofore constructed, regardless of speed, capacity, or head.

No opportunity to check the actual efficiencies of the installed units will present itself until the next low-water season, in the summer or fall of 1914, and it is to be hoped that those in charge of the operation of the plant at that time will present a full account of the tests, as they should prove of great interest to the Profession.

These questions received much study, in connection with this development, and it was decided to use vertical units principally because it is possible to obtain higher efficiencies with large capacity vertical than with horizontal units. The reason for this is that in the draft-chests of large horizontal units there are of necessity sharp bends

causing losses of head, and there are other losses from the confluence of streams in the draft-tubes of multi-runner horizontal units. The ideal draft-tube is obtainable with the single-runner, vertical turbine, in which the water is received from the runner at high velocity and conducted away with gradually decreasing velocity to the tail-race, with small loss of effective head from friction or other causes. Volute or scroll casings which, in the last few years, experience has shown to return the highest efficiencies, are impossible to obtain economically in large capacity horizontal units. Besides these considerations, there are other objections to horizontal units in large capacity low-head installations, such as the facts that the unit would be below the level of tail-water, under flood conditions the power-house required would have to be larger, and the structural features of the horizontal shafts for these large wheels would not be satisfactory.

With regard to single *versus* multi-runner vertical units, the following points deserve mention: The ideal scroll casing, by which the inflowing water is brought to the runner at a uniform velocity at all points, cannot be obtained with multi-runner turbines. The effect of multi-runner turbines on draft-tubes is to cause either sharp bends, thereby decreasing the efficiency, or, in an effort to avoid this, require the lengthening of the unit to uneconomical proportions.

The single-runner unit makes possible an ideal arrangement of the operating mechanism, by which it is at all times open to inspection in the operating chamber above the runner. Other advantages of this type are that it is possible to lubricate the gate stems with grease cups, and that there are fewer parts to get out of order.

The selection of speed involves a close study of the inter-relations of power, efficiency, and cost per horse-power developed. In general, other things being equal, the cost of turbines per horse-power developed decreases as the speed increases, the horse-power increases as the speed increases, and the efficiencies at part gate fall off greatly as the speed increases.

An illustration of this last consideration is shown by Table 5, which is a comparison of the efficiencies of these runners at different speeds, under a head of 68 ft. for this installation.

For this development the runner developing 18 500 h.p. at a speed of 100 rev. per min., was selected because a great increase in power was obtainable over the lower-speed runner, with only a small sac-

rifice of efficiency under full load, and the half-load efficiency held up well above that of the higher-speed runner. The consideration that the head would decrease in time of flood to 56 ft. argued against the adoption of a runner with a half-load efficiency as small as 73 per cent. It should be noted that these efficiencies and capacities are not the same as those guaranteed for the full-sized runner, but are those developed from Holyoke tests on model runners.

TABLE 5.

	Efficiency at:		
	94.8 rev. per min.	100 rev. per min.	120 rev. per min.
Developing full power	90.6%	89.5%	90.1%
Developing half power	80.0%	77.0%	73.0%
Full power	16 850 h.p.	18 500 h.p.	17 500 h.p.*

* This runner was smaller than either of the other two, which accounts for the lower power than at 100 rev. per min.

Thrust-Bearings.—The function of the thrust-bearing, as previously noted, is to transmit to the bridge of the generator frame the weight of all the rotating parts and, in addition, the water thrust. Prior to 1912, roller- and step-bearings were the types in general use in hydraulic turbines. As its name signifies, the roller-bearing depended on a nest of rollers to reduce the friction while transmitting heavy loads in motion. In some forms of step-bearings, the load is carried by hydraulic or oil pressure at the foot of the shaft. A combination of these two types is in use in some plants. In 1912 a bearing of an entirely different design, which previously had been introduced into steam turbine practice, was applied to the hydraulic turbine. In October, 1912—when the selection of thrust-bearings was taken under consideration—there were only thirty of these Kingsbury bearings in use, and they were mostly in steam turbines under unit pressures of from 300 to 500 lb. per sq. in. of bearing surface. One was in use at the McCall's Ferry Plant and one additional had been ordered. Fig. 14 shows this bearing.

The lower casting with the pockets is stationary, and is bolted fast to the bridge of the generator frame. The segmental castings, with the flat Babbitted surface and the circular pocket on the underside, are the bearing blocks or shoes. These bearing blocks are sup-

ported on disks, the upper surface of which is a sphere of large radius, the disks fitting into the pockets under the bearing blocks. A collar, securely fastened to the shaft and accurately machined on the lower surface, rests on the bearing blocks when the unit is completely assembled. As the bearing blocks rest on a spherical surface, they are free to turn slightly as if on a pivot. When ready for operation, the interior parts of the bearing are completely immersed in oil. The fundamental principle of operation of the bearing, as expressed clearly by the inventor, is "perfect automatic lubrication effected by the pivotal support of the stationary bearing blocks or 'shoes,' which permits the formation of an oil film, completely separating the sliding surfaces."

This bearing seemed to do away with the objectionable features of the roller-bearing, namely, large friction losses, high initial cost, inaccessibility, and wear of the moving parts.

The bearing placed in June, 1912, in a 10 000-kw. unit at McCall's Ferry, was under a load of 410 000 lb. at 94 rev. per min. (equivalent to a unit pressure of 350 lb. per sq. in. of bearing surface) and was inspected in October, 1912, after 3½ months of steady service. The Babbitted faces of the shoes had been scraped before being placed, and they still showed distinctly the marks of the scraper. The area of contact, as shown by the bright area of the Babbitt, had extended but slightly, showing that the wear had been negligible. A computation made from the rise of temperature of the oil supplied to the bearing indicated a coefficient of friction of 0.0008. The bearing is made accessible for inspection of the Babbitted surfaces by wedges under the shoes, several of which may be removed at once, without lifting the shaft. The bearings, as made for the McCall's Ferry Plant, had an outside diameter of 48 in. The shaft diameter is 21 in.

After a careful consideration of the claims for the Kingsbury bearing and an inspection of that in service at McCall's Ferry, it was decided to adopt it. As constructed, it is 42 in. in outside diameter and supports a load of 330 000 lb.

A duplicate oiling system has been provided for the lubrication of these bearings. There are two tanks, each with a capacity of 838 gal., on the high-tension floor, from which the oil flows by gravity to the casing of the bearing. Provision has been made for the supply of 15 gal. per min. to the bearings, but this quantity will be regulated as

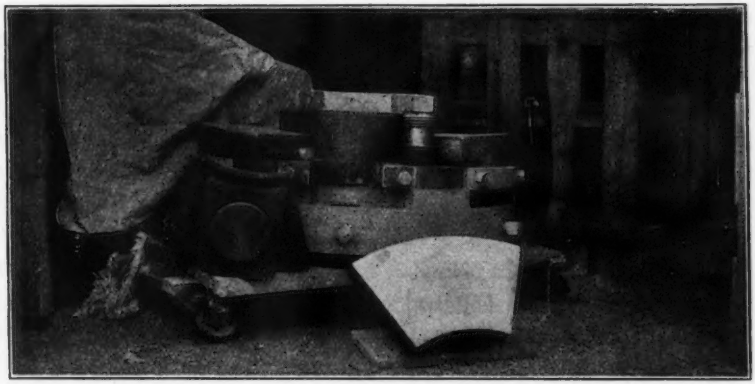

FIG. 14.—KINGSBURY BEARING.

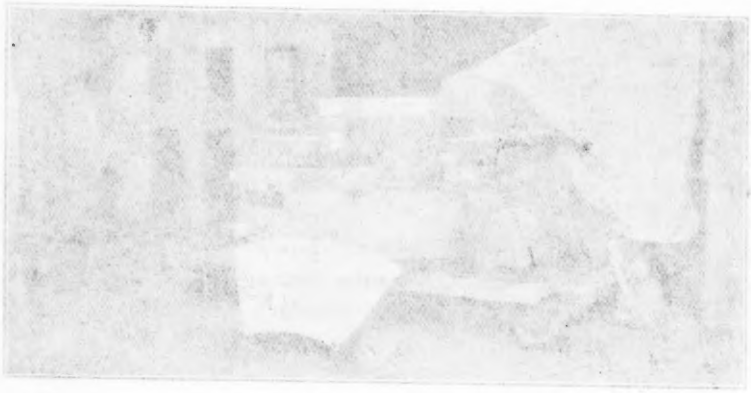
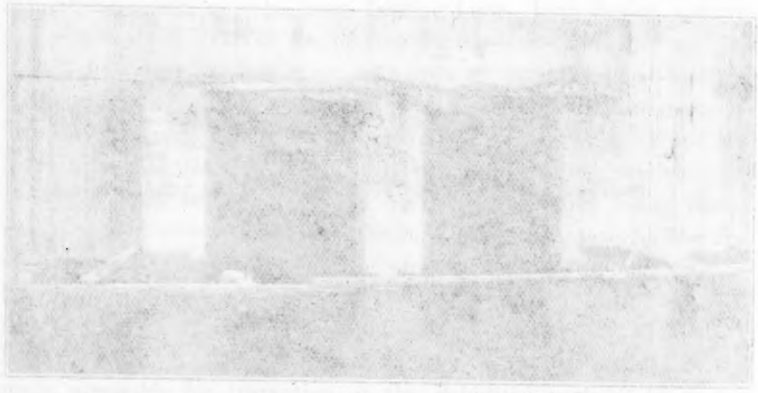
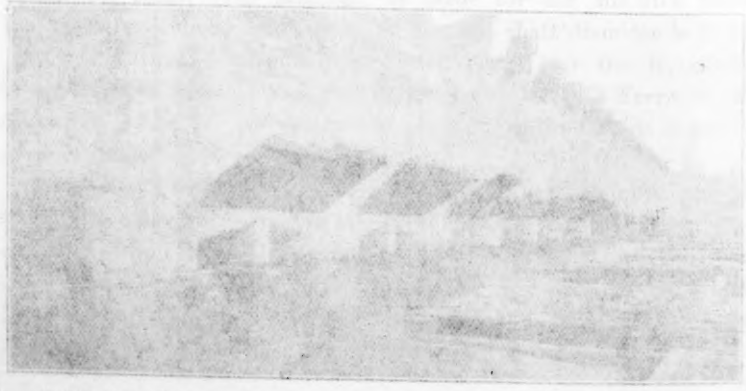
FIG. 16.—STREAM-CONTROL CONDUITS THROUGH DAM, WITH FLAP-GATES IN POSITION FOR CLOSING.







experience develops the best method of working the system. The temperature of the oil at the entrance to and exit from the bearing may be noted with the thermometers provided, so that the supply may be regulated. On leaving the bearing, the oil is pumped back through tanks, in which there are cooling coils, to the tanks on the high-tension floor. These coils are 2 ft. in diameter, are made up of 32 turns of 1½-in. pipe, and have a cooling surface of 105 sq. ft. No experience was available relative to the desirable capacity of these coils; their design is based on judgment alone.

Generators.—The four generators installed are 13 500 kv-a., 6 600-volt, 3-phase, 60-cycle generators, to operate at 100 rev. per min. The generator stator is mounted directly on the foundation ring of the turbine, to which it transmits the load received from the thrust-bearing.

The ventilation of the machine is effected by taking, through ducts in the concrete foundation, fresh air from outside the power-house and circulating it by the fan action of the rotor through the armature and out through holes left in the stator frame into the body of the power-house. The ducts provided for the purpose have a capacity of 60 000 cu. ft. of air per minute at a velocity of 2 000 ft. per min. The efficiencies guaranteed by the manufacturers are as follows:

Full load	95.7 per cent.
Three-quarter load	95.0 " "
One-half "	93.5 " "

Exciters.—Mounted above the thrust-bearing, and securely bolted to the main shaft, is the exciter. These exciters are of the shunt-wound type, with interpoles. The field frame rests on the generator bridge. They are rated at 150 kw., at 100 rev. per min., and 250 volts. An auxiliary motor generator exciter of 150 kw., 250 volts, is provided.

Governors.—The governors are four, modified Keokuk type, actuators, with independent motor-driven pumps, and tanks for the control of the double servo-motors furnished with the turbines. This apparatus is guaranteed, at 200 lb. per sq. in. pressure, to open or close the turbine gates completely in 2 sec., if not called on to develop a greater energy than 250 000 ft-lb. The governors are also

guaranteed to stand substantially steady when the speed does not vary, to be dead beat in action, and not to hunt, to correct with maximum promptness for all load changes within the capacity of the water-wheels to which they are attached, to maintain the speed steady within one-half of 1% under uniform load on the water-wheels to which they are attached, to begin to adjust the water-wheel gates when the speed has varied one-half of 1%, and to operate perfectly in parallel with one another.

Penstock Gates.—As shown on Plate XXV and Fig. 10, each penstock has two entrances, separated by a pier. This made it possible to reduce the size of the gates to 16 ft. 6 in. wide and 20 ft. 0 in. high. The penstock gates are of two types: one is equipped with rollers and a spring sealing device, and the other is a sliding gate with bronze wearing strips. One of each type is used on each penstock, the gate on rollers being opened first to facilitate the opening of the sliding gate. In general, the gates of both types are made up of 24-in. I-beams with $\frac{7}{16}$-in. buckle-plates, and properly stiffened (see Figs. 17 and 18). The gate-lifting apparatus, shown on Fig. 7, consists of a cast-iron cylinder for each gate, 30 in. in inside diameter and 20 ft. 11½ in. long. A piston attached to a 6-in. rod, 24 ft. 6½ in. long, is operated in this cylinder by oil pressure taken from the governor oil system. The cylinder walls are 1¾ in. thick, and were tested to 300 lb. per sq. in.

Spillway Gates.—On the spillway, as previously noted, there are 26 gates of a modified Stoney type, as shown by Figs. 19 and 20. Their over-all dimensions are 14 ft. high and 32 ft. 9 in. long. They are built up of four horizontal girders, 36 in. deep at the center and 18 in. deep at the ends, and buckle-plates. The horizontal girders are framed into box-girders at the ends, each of which carries two rollers. The same type of bronze sealing device is used as on the Type A penstock gates, and if this is found to be unsatisfactory in practice, it can be removed and a staunching rod readily substituted. Cast-iron guides, bolted to the ends of the gates and running in cast grooves set in the concrete, prevent the gates from blowing out of line in the wind when in a raised position. The gates are suspended at each end with flat steel ropes passing over drums at the top of the piers. The drums are actuated by shafting and gears, which may be operated from an electric hoist car mounted

Lock 12 Construction.

The construction of the dam and power-house at Lock 12, as laid out and built, is described in detail in the following pages. In considering the various features of this work, the paper is divided into four general headings.

Section A consists of a general outline of the work to be done, its location and description, its general features, and the methods which were planned and adopted for doing it.

Section B covers the methods adopted for handling the work, the materials used, the camps, railroad facilities, description and layout of the contractor's plant at the dam and quarries, the storage and care of materials, and the inspection of all work and materials.

Section C describes in detail the prosecution of the work and the various construction features—the coffer-dams, excavation methods, forms, mixing and placing of concrete, completing the work, and the final closure of the dam.

Section D covers the details of both the contractor's and the Alabama Power Company's organizations for handling the work in the field, their relations, and responsibilities.

Section A—General Outline of Work to Be Done.

Lands.—The land secured, in addition to the actual site of Lock 12, was as follows: On the east bank of the river, a strip averaging 1 800 ft. wide, back from the river bank, extending down stream below the line of the dam 1 400 ft. and up stream about 4 000 ft.; on the west bank of the river, on which all camps, contractor's plant, etc., were located, there was owned, in all, at the immediate site, a strip extending an average distance of 1 900 ft. back from the bank from a point 1 600 ft. down stream to a point 2 400 ft. up stream from the dam. This latter property was used entirely for construction purposes. Considerably more property was owned farther up the basin, but those mentioned are in the immediate vicinity of the dam site.

In addition to the lands described, at or near the site of the dam, on the west bank of the river, the timber rights to 3 250 000 ft. of lumber were purchased, and on the flooded lands purchased on the east bank of the river, there was another 1 000 000 ft., all of which was cut and used, furnishing nearly all the lumber needed for camps and other purposes.

Surveys at the Dam.—On August 5th, 1912, a party was put in the field at Lock 12 for the purpose of establishing the construction lines and elevations preparatory to starting the work. The tops of the 4-in. pipes, used by the U. S. Government for making shot borings on this site, were visible above the water surface, and the average line of these pipes was indicated as the up-stream face of the dam. This line was first permanently established, monumented, and thoroughly referenced, and an original stake, marked 1°, was established as Station 5 + 00 and so used on all surveys and drawings. This was the starting point of all measurements, and the stationing increased to the eastward from here. The up-stream face of the dam was considered as Station 0 + 00 for measurements at right angles, the stationing increasing down stream. In order that the main construction base line should fall inside the construction limits, a line parallel to and 10 ft. south of the face of the dam was run in, and all work was referred to this base line. Concrete monuments, with railroad spikes embedded in them and center-punched on line, were established on this 10-ft. line, at intervals of about 90 ft., for a distance of 1 000 ft. on each end back from the water's edge. On the west bank, to guard further against loss of lines, one of the monuments was carefully referenced. The original elevation left at this point by the Government was permanently established, and all work was based on it. All surveys of overflowed lands were based on this same datum, and deeds written were referred to it as their basis.

A diamond drill outfit was put on the work about August 5th, 1912, and a series of borings was made across the river, on the line of the up-stream face of the dam, in order to verify the original Government data.

Contract for Substructure and Dam.—A contract, under date of August 1st, 1912, was entered into for the construction of the substructures of the dam and power-house, and under it the work was

prosecuted to completion. It was of the cost-plus-a-fixed-fee type, in which, however, the Power Company, through the Engineering Department, had unlimited powers in the direction of the work, and exercised close supervision over all its details. The general requirements of the contract called for completion by December 31st, 1913.

The purchase of all materials was subject to the approval of the Power Company before orders were placed or any contracts made, and payments made under the contract were divided into three general items: (*a*), (*b*), and (*c*).

Item (*a*) covered the contractor's fixed fee;
Item (*b*) covered rental on plant owned by the contractor; and
Item (*c*) covered all expenditures made by the contractor in the prosecution of the work.

About one-half of the large plant was rented from the contractor, at a certain percentage per month, on an agreed valuation, and a list of the items of this plant was attached to and made a part of the contract. The selection of all plant used under Item (*b*) was subject to the approval of the Chief Engineer. Under Item (*c*) were made all expenditures in the prosecution of the work, and they were subject to approval by the Chief Engineer for all that were not the usual running items. The usual camp expenses were covered under a general approval. All plant actually purchased, the operation and maintenance of the railroad, and like items, were included under this item of the contract.

Sources of Materials, and Methods of Securing and Handling Stone, Gravel, and Sand.—Some time before the work was begun at the dam, investigations of all the surrounding country were inaugurated, for the purpose of finding suitable concrete materials for use in the dam. Prospecting parties were put in the field in the early part of August, 1912, to find sand and gravel pits, or stone quarries, as near the dam as possible. These investigations showed that all rock at the dam site, and for several miles up and down stream, would be unsuitable for concrete purposes, being a thin-bedded slate with numerous quartz seams running through it. No sand suitable for concrete was found at all. Gravel, in small quantities only, and in pockets, was found along the river, and such

sand as was found with it contained such high percentages of clay as to render it unfit for use without thorough washing. Early in the work, therefore, it became evident that sand would have to be secured from outside sources.

The only suitable stone in the district was found, after several months of prospecting, near Zion Church, in Sections 17 and 18, Township 23 N., Range 15 E. (see Fig. 3), and its area was more or less restricted. After carefully prospecting this site at Zion Church and another hill about a mile distant, known later as Ellison Quarry, both sites were purchased. All surface indications and drill borings indicated that Ellison Quarry would be the better of the two; later, however, the contrary turned out to be the case. Both sites were about 11 miles, *via* the construction railroad, from the dam, and were the only available sources of coarse aggregate and cyclopean stone found in the vicinity. Both these hills were heavily overburdened, and, after opening up Ellison Quarry and working it for several months, so many clay seams showed throughout the rock that it had to be abandoned. Although there was plenty of suitable rock available at Zion Quarry, it was only possible to work five derricks, and the stone could not be quarried with sufficient rapidity to satisfy the demands. For this reason, gravel and stone were secured from outside pits to fill out the supply. All the crushing operations were carried on at Zion Quarry, and a general view of the quarry and its layout is shown in Fig. 21.

A chemical analysis of the stone furnished from Zion and Ellison Quarries was as follows:

Aluminum and iron oxide	3.44 per cent.
Carbonate of lime	50.83 " "
Silica	9.00 " "
Carbonate of magnesia	36.38 " "
Combined water and organic matter	0.35 " "

The stone proved to be of excellent quality for concrete purposes, and was far superior to any purchased from outside commercial quarries.

All sand was furnished by contract at a price not to exceed 25 cents per cu. yd., f. o. b. cars, at Jackson's Lake, near Montgomery, Ala. There was a freight charge of approximately 70 cents per cu.

FIG. 21.—CRUSHER PLANT AT ZION QUARRY, SHOWING ALSO PORTION OF STORAGE BIN.

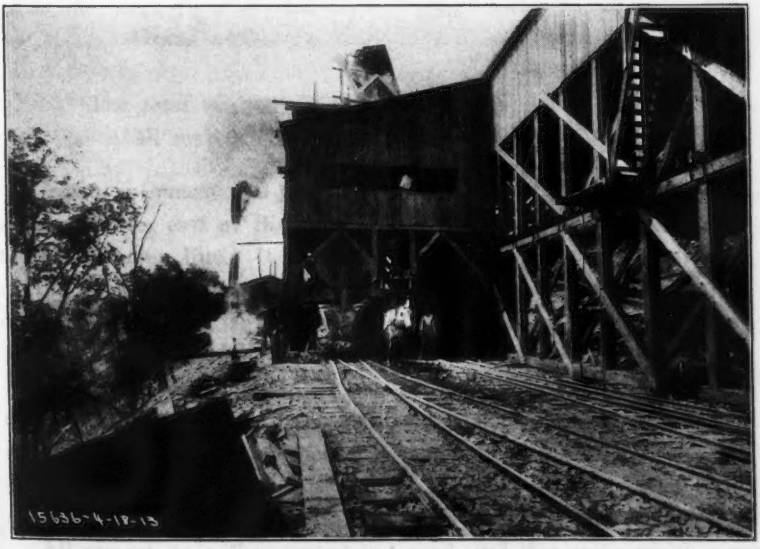

FIG. 22.—CONCRETE-MIXER PLANT.

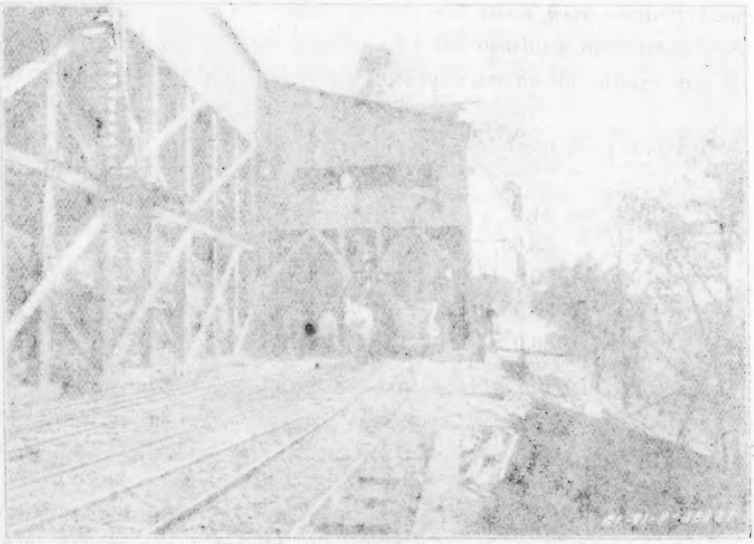

yd. from Jackson's Lake to Ocampo, making the total cost per cubic yard at Ocampo, 95 cents. This sand proved satisfactory, although certain sections of the pits contained a good deal of loam, and it was necessary for the Power Company to maintain an inspector there constantly to supervise the loading and subject the sand to certain quick field tests for percentages of foreign matter.

All gravel secured from outside sources was washed, with the exception of that brought from the Company's pit at Elmore, Ala., which contained about 45% of gravel and 55% of sand. This pit was purchased to help out at the height of the concreting, and served its purpose.

The following tabulation shows the quantities of materials secured from various sources:

Crushed stone from Ellison Quarry....	11 031 cu. yd.
Crushed stone from Zion Quarry.....	115 207 " "
Cyclopean stone from Zion and Ellison.	7 670 " "
Stone purchased from outside sources.	13 998 " "
Washed gravel from outside sources...	31 031 " "
Elmore gravel (60% gravel).....	6 009 " "
Grand total.....	184 937 cu. yd.

The total quantity of sand used from all sources was..... 57 809 cu. yd.

Cement.—Cement was purchased from local mills, one in Alabama about 40 miles east of Birmingham and the other in Tennessee close to the Alabama line. It was tested at the mills by representatives of the Power Company, under the specifications contained in *Circular* No. 33 of the U. S. Bureau of Standards.

The cement was delivered to Ocampo in carloads of approximately 170 bbl., at a cost of $1.30 per bbl. net. At the dam site a weather-proof storage shed with a capacity of 15 000 bbl. was built and kept full until the work was nearly completed, when the storage was drawn on to tide over periods of car shortage caused by the cotton movement.

All cement, as well as gravel and sand, and that stone which came

from outside quarries, was contracted for by the Company and delivered to the contractor at Ocampo.

Lumber.—Rights to approximately 4 000 000 ft. of timber were acquired in the vicinity of the dam, and contracts were let locally to three small mills to cut it. All these mills were within a mile of the dam, and the sawed lumber was teamed by the Company to the point needed. It is to be noted here that, whenever possible, saw-mills should be on the construction railroad, or should have railroad service.

Timber proved to be very cheap in this section, the price of all the lumber used, of all classes, being about $10 per 1 000 ft. b. m. at the dam.

All the lumber for coffer-dams, camp buildings, bins, shops, stores, forms, etc., was supplied by the above timber and mills. Approximately, 6 600 000 ft. of lumber for all purposes—railroad, dam, and quarries—were used.

Commissary Supplies.—Practically all commissary and other running supplies were secured in the Montgomery or Birmingham market, being bought directly by the contractor. Before the construction railroad was ready for service, all these supplies were brought to Clanton, Ala., 13.6 miles from the dam, by road, and were teamed to the dam by local teams at 20 cents per cwt. Later, when the railroad was in service, a regular merchandise car was run by the Louisville and Nashville Railroad Company from Birmingham to Ocampo and thence taken to the dam on the Clear Creek Railroad. An arrangement was made with the Louisville and Nashville Railroad Company to run a regular package car exclusively for the work at the dam, and during the height of the work, there were two, and sometimes three, cars of merchandise daily to take care of the large force at work.

Coal.—Coal was contracted for by the contractor and delivered in hopper-bottom cars, *via* the Louisville and Nashville Railroad, at Ocampo, from which place it was carried on the construction railroad to the points desired. At the quarry and dam the coal was dumped through trestles directly in front of the boilers where it was to be used. On the railroad it was shoveled by hand out of the cars for engine uses directly into the tenders or to buckets moved by air hoists.

Coal was bought from various mines in Alabama, at a price of $1.50 per ton, at the mine, and a freight rate of $1.00, making the price, f. o. b. Ocampo, $2.50 per ton.

General Scheme of Handling Work at the Dam Site.—The general scheme and outline laid down and followed for the prosecution of the work contemplated the building of three coffer-dams and the handling of the work as follows:

1st.—Coffer-dam No. 1, which took in the west abutment, power-house, wasteway section, and 404 ft. of the dam, was built and the work within it excavated and concreted. This coffer-dam was designed and built to care for a flow of 75 000 sec-ft. in the river without flooding, and accomplished its purpose. Sufficient openings were left through the portion of the dam constructed within Coffer-dam No. 1 to care for a flow of 20 000 sec-ft. without flooding Coffer No. 2. The work within Coffer No. 1, it was anticipated, would be accomplished during the high-water stages of the river and that in Coffer No. 2 during the low-water, summer season.

2d.—The building of Coffer No. 2, turning the river through the culverts left in the first portion of the dam.

3d.—The construction of the second portion of the dam and east abutment, leaving more openings through it, with their bottoms at a higher elevation, in order to be able to pass a large flood if the river rose rapidly in the fall before the power-house end of the work was finished, and also making it possible for the reservoir to be drawn down if the water did rise to a considerable height before the work was completed.

4th.—The construction of the tail-race coffer-dam at about the same time as Coffer No. 2, and the excavation of the tail-race while the second section of the dam was being concreted. The power-house concreting was to be prosecuted while the first section of the dam was being built, but it was anticipated that it would be far behind that portion of the work, and would come to completion about the same time as the second section. Consequently, a small concrete wall, from the end of the power-house next to the wasteway section up stream, and a coffer-dam down stream to the tail-race coffer, were built in order that when the water was turned through the first section of the dam, the power-house and tail-race work would still be protected.

Section B—Methods Adopted for Handling the Work.

Camps.

The very first problem which presented itself in the prosecution of the work was the building of camps, and the providing of necessary messes and quarters for the men and houses for their families, as it was realized that unless there was proper food and comfortable habitations, it would not be possible to hold the men. It was anticipated that a very large force would be necessary in order to complete the work quickly and on time, and that, with such a large force, the sanitary and medical part of the work would need strict attention, and would be no small problem in itself. It was also essential that no contagious or infectious disease be allowed to gain a foothold and sweep through the camps, seriously hampering the work and giving the job a bad name. All camp buildings were constructed of wood, and were fairly well ventilated and cared for.

Lock 12 Camp.—At the dam five distinct sections of the camp were built. The white camp contained the commissary, white mess hall, bunk-houses, foremen's houses and families, and the houses of the contractor's staff, ice plant, bakery, storehouse, etc., in fact, this was the main camp. The engineers' camp was by itself, near the contractor's main camp No. 1, and contained a bunk-house, family dwellings of the staff, a mess hall, office, and a special house for the accommodation of Company guests and visitors, known as the "Guest House." The negro quarters were about ½ mile from the main camp, on one side of the railroad. About 400 yd. from the negro quarters was a fourth camp, for foreigners. The Swedish carpenters lived in a camp by themselves. The camps for the negroes and foreigners were combined into one large negro camp after the foreign laborers at the dam were discharged. Fig. 23 is a general map of the Lock 12 yards, railroad connections, etc.

About 1 000 persons could be accommodated at the main Lock 12 Camp, and at the height of the work it contained about that number. The topography at Lock 12 prevented any general scheme of laying out the buildings; they were placed on the tops of the ridges, with the drainage away from them toward the river and creeks. Where possible, a regular arrangement should be adhered to, and is also recommended from a sanitary standpoint. Some of the bunk-houses at this camp were too large, and did not afford proper ventilation at

night. A house of proper size would be one large enough to accommodate twenty men, well ventilated, and, in the skilled and white quarters, there should be a shower bath in each house. In the negro camp, a large mess hall and several houses were provided. This, however, is not the best system to follow in handling the negro. A large number of small houses, with no general mess hall, the writers believe, would be better, and, later, this scheme was used, and is being used by other contractors on similar work in this section of the country to good advantage. To hold the negro laborer on the work it is essential that he have his negro women with him, as he will not stay in the camp unless the women are there. Consequently, provision has to be made to take care of them. Another feature of holding the negro is that he be allowed to shoot "craps" and play "skin", his favorite pastime and card gambling game, and it is useless to try to stop him. The local county authorities realized this here, and arrangements were made whereby the negroes did all their gambling and card-playing in the confines of their own quarters, where they were not molested.

In the Italian and foreign camps, no mess halls were provided, as laborers of this class prefer to board themselves. However, a bakery had to be established to provide the kind of bread especially preferred by them, and from 500 to 1 000 loaves per day were baked and distributed to the various camps.

In general, the buildings, as used, proved serviceable and efficient, but one error was committed, in a part of the camp, in placing them too close to one another. A fire in the negro quarters, which should have destroyed only one building, destroyed six, due to this cause.

In addition to the living and eating quarters described, a schoolhouse was erected for the white children, and used also for religious gatherings. A church was also built in the negro quarters. No recreation rooms were provided, and the writers consider this a mistake. A large, airy, reading and writing-room should have been provided for the white camp. It should have been in charge of a competent man, and operated at the Company's expense. It is the opinion of the writers that, with a place of this nature provided for the men, a certain amount of drinking and gambling can be eliminated, and, furthermore, the superintendent can put his hands on some of the men quickly in times of emergency.

A small 1½-ton ice plant was installed at the rear of the white kitchen at Lock 12, and, adjoining both the plant and kitchen, there was a large cooling room, where all meat for the camp was kept fresh. This plant did not prove quite sufficient for the Lock 12 camp in the hottest weather, and the supply for the other camps had to be contracted for from outside sources and hauled in daily by team. The plant proved satisfactory except as noted.

Water for the camp at the dam was secured from two sources. That used for drinking purposes came from drilled wells, 6 in. in diameter, and more than 130 ft. deep, one in the negro camp and one in the white camp. Water was circulated through the white camps from this well by a gasoline pumping outfit. For other purposes the water was pumped from Yellow Leaf Creek, ½ mile distant, by a steam pump, to a 20 000-gal. tank set on a tower in the highest part of the camp, from which mains distributed it throughout all the camps for fire, boiler, and locomotive purposes, baths, washing, etc. This water was not used for drinking on account of danger from typhoid infection.

Quarry Camps.—Houses of the same general types as those at the dam were used at the quarries, except that, in the Italian quarters, little kitchens were provided in which these people could do their own cooking. In the negro section of this camp there were tents, with floors and wooden sides half way up and permanent wooden frames. A commissary was run at Zion Quarry, which took care of both Ellison and Zion Quarries, and provided for the general mess hall and the individual messes. Bread was secured from the Lock 12 bakery, and ice, to keep the meat, etc., fresh, was hauled by team from Clanton. Ellison Quarry, while operating, had a small commissary run as a subsidiary to that of Zion Quarry. Water was provided at the quarries by wells, from 100 to 150 ft. deep, drilled with a regular well-drilling rig.

Lighting of Camps.—Steam-driven lighting plants were provided at the dam and at Zion Quarry, and furnished lights to all houses, shops, storehouses, etc., and the general camp and job lighting. Dwellings were supplied with light, at an equitable rate, if so desired. Flaming arc lamps were used on the work proper and for general lighting throughout the camps. Later, when the transmis-

sion lines were connected up to Gadsden, the steam plant was shut down at Lock 12, and current was secured from this source.

Hospital, Medical Service, Sanitation.—All medical and hospital service was handled under a contract with a local physician who lived at the dam. Under the contract he was to render services at all the camps, provide all drugs, medicines, a hospital, nurses, etc., and receive in return 90% of the collections from the men, which amounted to $1 per month per man.

The doctor also acted as sanitary officer, but merely reported what he saw and had no authority to enforce his rulings, which was not a desirable feature. Sanitary precautions were taken by providing the pail system of closets and making the boxes of the closets fly-proof. The refuse matter was gathered nightly by a sanitary wagon, hauled a considerable distance from camp, and buried. All closets were kept well sprinkled with lime at all times. All kitchens and dining-rooms were screened, as well as practically all the family dwelling-houses.

The general health of all the camps was remarkably good. No contagious or infectious diseases originated at any of them. At the quarry camp several cases of typhoid fever developed among the Italians, and was traced to some bad meat which they had secured from an outside source. Only about six or eight cases came from this source, one of them being an inspector on the Resident Engineer's staff.

All accidents were treated immediately by the resident physicians, at the camps in which they occurred, and serious cases were brought to Lock 12 to the general hospital, where nurses were maintained.

Policing the Camps.—A regular force of deputies was maintained by the Power Company, regularly commissioned under the Sheriff of Chilton County, there being two deputies at Lock 12, one at the quarry, and one on the railroad. The most troublesome features arose from bootleggers bringing whiskey into the camps.

Camp Bosses.—Camp bosses looked after the cleaning and care of the camps; and their assistants, known as shack rousters, looked after the cleaning of the bunk-houses, etc. In the negro camp, the camp boss was a responsible white man who thoroughly understood the negroes and saw that they were not allowed to lie around

the camp, unless actually ill. He kept track of the various families occupying the small houses, looked after the checking of the dining-room, kept his eye on bad negroes, and, in general, maintained order. He also assigned quarters to new men coming in and looked after them, seeing that they got out to work properly.

Layout of Contractor's Plant and Details of Various Main Parts of the Plant.

Railroad Yards and Tracks.—At Lock 12 extensive yards and tracks for the storage and rapid handling of materials were provided; and a line was built down into the river bottom, below the dam, whereby trains and engines could get down on the cofferdam; this was known as the "Low-Level Line." There were two storage yards for sand and gravel where loading and unloading operations in no way interfered with regular train and switching movements. A long side track served the main cement warehouse, oil house, and general store-house, so that cars were unloaded directly into them. The shops were also served with another siding, but the arrangement used was a poor one, and detailed criticism of this feature of the layout is given elsewhere. The main line, known after it left the yards on its way to the dam as the "High-Level Line", served the mixer, cement warehouse, concrete material bins, and compressor plant, materials being unloaded directly to these various places from the cars. Fig. 23 is a map showing this detailed track layout.

Cableways.—Two traveling cableways spanned the river parallel to and immediately over the face of the dam. Together, the two cableways had a range of about 150 ft. up and down stream, that is, one could be placed over any portion of a strip 150 ft. wide at right angles to the line of the dam. The towers of these cableways were 95 ft. above the rail, their track elevation being about 440. The length of span, from center to center of towers, was 1 647 ft. The towers traveled on standard-gauge tracks and on standard M.C.B. car wheels and axles. The main cables were 2¼ in. in diameter and of patent, lock-laid, flat, steel strands on the outer covering. The cableways were also equipped with one button line, having eight buttons on it, one endless line, and one hoist line. The button and hoist lines were ¾-in., $\frac{6}{25}$-strand, Hercules, wire ropes.

The endless line was a $\frac{3}{4}$-in., $\frac{6}{25}$-strand, flat, wire rope. The button line was 1 700 ft. long, the hoist line, 2 100 ft., and the endless line, 2 600 ft. long. The cableways were operated by $12\frac{1}{2}$ by 15-in. engines, driven by steam, supplied from 80-h.p., locomotive-type boilers, all mounted on the trucks of the towers. The cableways had a rated capacity of 10 tons, and were operated under a sag of 80 ft. with a load of 6 tons.

In the early stages of the operation of the cableways, a good deal of trouble was experienced with carriers. The original carriers seemed to be too heavy, frequently breaking each other when they struck. Lighter carriers were made, and much of the trouble was eliminated.

Trouble was also caused by the breaking of two strands in No. 2 cable. The first breaks were welded by the oxy-acetylene process. The weld did not prove satisfactory, and they broke again; this cable was used for the remainder of the job with these strands cut out.

The buttons used on the button lines were of an obsolete type, and were not satisfactory; when one of them broke or slipped along the cable, it was necessary, in order to put on a new one, to lower the cable, cut out a section, and replace it, all of which was expensive and caused much delay. There is now manufactured a cast-steel button, made in two parts, which does away with the necessity for lowering the cable. A button of this type can be put on in an hour, and is a great improvement over the old one.

Extra hoist, button, and endless lines were kept in readiness at the head-towers, so that, in case of a breakdown at any time, they could be quickly and rapidly installed. The cableways handled practically 60% of the concrete, and were run both day and night. They also handled practically all the excavation in the early stages of the work. They were used for moving and erecting all derricks, etc., handling form lumber, iron, and materials of a like character, and were found to be exceedingly useful for the latter purpose.

Derricks.—All derricks used at the dam for excavating and placing concrete were of 5-ton capacity, of the wooden, traveling, stiff-leg type, with 37 to 40-ft. masts and 55 to 65-ft. booms. These derricks traveled on the up-stream and down-stream coffer-dams, parallel to the line of the dam, and on the bottom in the tail-race

and draft-tube excavation of the power-house. Later, when the concrete reached Elevation 380.0 in the power-house, three of these derricks were set up on high bents and were stationary.

All the derricks were equipped with $\frac{5}{8}$-in., $\frac{6}{19}$-strand, Hercules, steel-wire rope hoist and boom lines, and with 14-in. derrick irons and 12-ft. bull-wheels. Double blocks were used on the booms and single blocks on the hoist lines, and were operated by 7 by 10-in. engines, with swinging gears, driven by air. The traveling feature of these derricks seems to be an excellent one, as their increased radius of action is most advantageous. In this case the back trucks of these derricks traveled on the top of the coffer-dam, and the front trucks on a trestle resting on the bottom inside. Three of them were able to cover a length of 475 ft. of the dam, on the up-stream face. These derricks handled excavation in skips into cars run out on the up-stream coffer, and took concrete from the cableways, placing it in the forms, the cableways depositing a loaded bucket in a certain place and removing the empty bucket, the derrick then taking the bucket and dumping it in any portion of the form desired. They also took concrete from flat cars run out on the up-stream coffer-dam.

Mixer Plant.—The mixer plant was about 200 ft. south of the cableways, and discharged concrete to cars standing at Elevation 425. The plant consisted of two Model 64, 84-cu. ft. mixers, owned by the Power Company, and driven by an 18 by 24-in., horizontal, single-cylinder engine, rented from the contractor. This engine was run by steam supplied from the compressor plant, about 100 ft. away, as shown in Fig. 22. These mixers had a capacity of 20 batches per hour, their combined capacity being 3 200 cu. yd. for two 10-hour shifts. The highest run made was 2 220 cu. yd. Materials for concrete came in in hopper-bottom cars, and were dumped through a trestle into a bin having a capacity of 800 cu. yd. They were removed from this bin by a belt conveyor to a bucket elevator, and deposited in smaller bins over each mixer, from which they were drawn to the measuring hoppers. The belt conveyor and bucket elevator were driven by a 10 by 16-in., horizontal, single-cylinder, engine, also run by steam supplied from the compressor plant. The drive on both the mixers and elevators was with belts, to line shafts, and friction clutches. One of the drums of the mixers wore through,

comparatively quickly, due to the exceedingly tough and hard quality of the stone. This drum mixed approximately 70 000 cu. yd. of concrete. These drums were of ¼-in. metal, and the writers believe this to be somewhat too thin for this size. They suggest that a ⅜-in. shell would be preferable. Four sets of blades and one drum were worn out on one mixer, and three and one-half sets of blades on the other, in the course of the job.

Two elevators were installed during the progress of the work. The first was a No. 6, 18-in. bucket, stone elevator, 67-ft. centers, on the main pulleys. It did not have sufficient capacity to supply 1 000 cu. yd. per 10-hour day to the mixers, as required, and was taken out in August and replaced with a No. 8, 30-in. bucket elevator. A 32-in., 6-ply belt, 147 ft. long, was used, and had ninety-eight 30 by 17 by 10-in. steel buckets. After the installation of the larger elevator, there was no more trouble.

Water.—Water was supplied to the mixers through a 2-in. line from the main storage tank at the dam. Two small iron tanks with the necessary control valves, gauge glasses, etc., were equipped and set up overhead in the mixer-room, and all the water was drawn directly from these to the mixers.

Empty Sacks.—As soon as the cement was emptied into the hoppers, two laborers assigned to the duty gathered the sacks, shook them off to one side, packed them in bundles of 50, and stored them in the mixer cement house until from 20 000 to 30 000 sacks had accumulated, when a carload was shipped to the mills. The sweepings were sacked and used with the other cement.

Compressor Plant.—Practically all derricks, hoists, small pumps, air drills, small wood-boring tools, etc., were operated by air at a pressure of 85 lb., furnished by a central compressor plant which was near the mixing plant. The boilers of this plant also furnished steam for driving the mixing plant.

Two 24 by 30-in. straight-line air compressors, each with a capacity of 1 225 cu. ft. per min., furnished all the air. These machines were leased with other equipment from the contractor. The compressor and the mixer plant were supplied with steam by four 125-h.p. horizontal, locomotive-type boilers, leased from the contractor.

The compressors delivered air at 85 lb. pressure through a 6-in. main to a storage tank, 4 ft. 9 in. in diameter, 12 ft. long, and of

⅝-in. metal, located outside the building. A system of pipes was arranged to spray water constantly over this tank to keep it cool, and a special grade of oil was used in the compressors on account of the likelihood of explosion in the storage tank. The air was distributed to the principal points of use through a 6-in. main.

The construction of the compressor plant was commenced on November 16th, 1912, and the first compressor was turned over on January 14th, 1913. The plant was entirely completed and ready for business on February 1st, 1913.

Machine and Carpenter Shop.—The machine, carpenter, and blacksmith shops were all in one long building in the yards near the main storehouse. One line shaft, 84 ft. long, ran through the length of the building, and all machine tools were driven from it. The engine driving this line shaft was an 11 by 14-in., horizontal, single-cylinder engine owned by the Alabama Power Company. It was supplied with steam by a 30-h.p., vertical boiler, leased from the contractor. The engine and boiler-room was in the center and at the rear of the shops.

The machine shop contained the following tools:

One 30-in. radial drill press,
One 24-in. shaper,
One 18-in. by 10-ft. lathe,
One 1½-in. bolt threading machine,
One No. 94 Forbes, 2½ to 6-in., pipe cutting and threading machine,
One 16-in. by 5-ft. lathe,
One 30-in. diameter by 5-in. face power grindstone, and
One No. 4 Vulcan emery grinder.

The blacksmith shop contained the following:

One No. 2 Champion blower for forges,
Three blacksmith forges, home made,
Three anvils, from 250 to 300 lb.

The carpenter shop contained:

One No. 8 variety rip-saw and joiner,
One band saw,
One No. 402 bench grinder,

One No. 8 planer and matcher. This planer was very useful, and surfaced all form lumber; if the saw-mill had been operated by the Company, however, the planer should have been there.

The writers consider that the foregoing equipment served its purpose well, but there should have been added to the machine-shop a power hack-saw, a set of shears large enough to cut rounds up to 1 in. in diameter and flats up to 1 by 3 in., and a small steam-power hammer, on a job where there are a number of locomotives and cars to be taken care of.

The shops, as located, did not have sufficient floor and working space, and should have been separated from each other. Both should have been closer to the dam, and served by independent spurs from the railroad, so that cars of lumber could have been delivered to the platforms and yards direct. The laying-out floor of the carpenter shop should have been large enough to build one complete scroll case form on it, which would have taken a platform 75 ft. square. Also, there should have been a second laying-out floor, at least 50 by 100 ft., for ribs and other work of that kind.

The machine shop, if possible, should be as close to the work as convenient for all purposes, and should have at least two tracks for its own exclusive use: one for bringing machinery, etc., to be repaired at the shop; the other to serve as a general rip yard track. Where a railroad is operated and engines are taken care of, a pit for dropping wheels should be provided on one of these tracks.

Locomotive Cranes.—Two 10-ton locomotive cranes were leased from the contractor, and used in all features of the work. They did the work well, but the type used had only four wheels, which was hard on the track when traveling around. Two 1½-yd. clam-shell buckets were furnished with these cranes, and were used for unloading, storing, and reloading from storage all sand and gravel, and for coaling engines, etc. They were also used to assist in the disposal of excavation from the dam and tail-race, handling loaded skips. They were also used in unloading and erecting the contractor's plant and in reloading it when the work was completed. They were found exceedingly useful all through the work, but were not quite big enough for all purposes. After the work was started a larger crane was purchased, having a 50-ft., fixed boom and a 30-ft., trussed extension. This crane had a capacity of from 20 to 30 tons at 12 ft. radius, and

was used at first for stripping at the quarry and loading cyclopean stone. Later, it was used in erecting the steel framework of the power-house and handling the heavy castings and machinery going into it.

Quarry Plant and Layout.—Fig. 24 is a general map of the layout at the quarry. The following is a description of the various pieces of plant and machinery used there: In general, the plant consisted of a crushing outfit of two McCully crushers, with necessary elevators for storing in a large storage bin, and a compressor plant for the operation of derricks, drills, pumps, etc.

Crushers.—Material brought from the quarry in skips was dumped by a derrick into a No. 9 gyratory crusher, leased from the contractor. After passing the No. 9 crusher, the stone was elevated by a No. 9, geared-head stone elevator having a 36-in. belt, traveling on 32-ft. centers, approximately 75 ft. long, equipped with fifty-two 37 by 18 by 11-in. steel buckets, to a revolving screen, 60 in. in diameter and 12 ft. long, mounted on a wooden frame. The perforations in this screen were 3½ in. in diameter. The belt, elevator, and screen part of the plant was owned by the Alabama Power Company. Stone which would not go through the screen was discharged into a No. 7½ gyratory crusher, also rented from the contractor. The final crushings were delivered to a 30-in., geared-head, belt conveyor, traveling on 270-ft. centers, over a 30-in. self-propelled tripper. The belt was 552 ft. long. The first belt wore out and was discarded in October for one of canvas, stitched.

The crushers, elevators, and screens were driven by an 18 by 27-in., horizontal, single-cylinder, non-condensing engine, which was rented from the contractor.

The belt conveyor from the crushers, to the storage bins was driven by an 8 by 10-in., horizontal, single-cylinder engine, purchased by the company.

Steam for both these engines was supplied from the compressor-plant boilers, a short distance away.

Compressor Plant.—The compressor plant consisted of four 18 by 24-in., straight-line compressors, having a capacity of 670 cu. ft. per min., and were rented from the contractor. This plant could operate a maximum of nine drills and six derricks. The plant was

not quite large enough for the needs on this work, and one more boiler and compressor would have been more satisfactory.

The compressors and other engines were supplied with steam by four 100-h.p., and three 75-h.p. horizontal, locomotive-type boilers, all leased from the contractor.

A coal trestle, 12 ft. high, was built immediately in front of the boiler-room, and hopper-bottom cars of coal were shunted to the top of it and dumped through. The coal was thus unloaded with a minimum expense at the point of use.

Derricks.—For handling stone out of the quarry proper there were six latticed-frame, steel-guy derricks, three of which had 75-ft. masts and 70-ft. booms, and were owned by the Power Company; and three had 65-ft. masts and 60-ft. booms. Each had a capacity of 10 tons.

These derricks proved to be somewhat weak for the work, and the bottom third of the mast had to be reinforced with four 30-ft., 60-lb., steel rails. These derricks were also very difficult to repair, for when a boom fell, or the derrick itself fell, it was generally badly bent. Timber derricks would have been better in this section, where a 70-ft., long-leaf, yellow pine stock, with a 12-in. top could be obtained for $25.

There was also one timber guy derrick, with a 73-ft. pine mast and a 68-ft. pine boom, using 14-in. derrick irons, the timber for it being cut from the Company's land. This derrick was placed at the crushers, and handled skips of stone from flat cars to the crushers.

All the engines on these derricks were 7 by 12-in., 24-h.p., double-cylinder, double-drum hoists, and fitted with size 3½ Dake swinging engines. This rig proved satisfactory, and was considered a good one for the work.

Miscellaneous.—For washing the crusher muck before it went to the crushers, and cyclopean stone, a No. 11, 6 by 10½ by 18-in. pump, steam-driven, was set up in the boiler-room. It had a capacity of 450 gal. per min., and furnished water, at 60-lb. pressure, through three 2-in. hose lines with 1-in. nozzles. The men stood on a washing platform and directed the water on the skip loads of stone just before they reached the crushers.

For pumping the quarry pit an 8 by 5 by 13-in. pump, having a capacity of 100 gal. per min., was found amply sufficient.

The heavy drilling in the quarry was done with No. 14, gasoline, portable, blast-hole, well drills. These were driven by a single-cylinder, gasoline engine, and drilled a 5⅝-in. hole, the whole outfit being mounted on the same frame, on trucks.

The lighter drilling was done with Ingersoll-Rand, E 24, rock drills, equipped with No. 44 air heads, No. 42 chucks, and No. 27 tripods, with weights.

A blacksmith shop with two forges was maintained at the quarry for the running work there, and also a No. 3 Leyner drill sharpener, which took care of the sharpening of all drill steel. It was operated by air, and was a great money and time saver. Where a great deal of drill work is done, and there is a large quantity of steels to keep sharpened, a tool of this kind should be used.

As a whole, the quarry plant was satisfactory and the layout good. The plant had a capacity of 2 000 cu. yd. of crushed stone per day, but the largest day's run was a little more than 1 000 cu. yd.

Storage and Care of Materials.

Two yards were provided for the storage of sand and gravel, and were served by spurs leading off the main line of the railroad west of the yards at Lock 12, as shown on Fig. 23. Each spur branched into a double track after leaving the main line, so that a locomotive crane operating on one track could unload a string of cars on the other without having them switched. Structural steel was also unloaded and stored in one of these yards. In addition, 1 600 cu. yd. of sand were dumped through a high trestle next to the compressor plant and about 300 ft. from the mixer bins. Run-of-pit gravel (containing about 55% sand) from Elmore was stored in the same piles with the sand. Washed gravel was stored in separate piles. At the quarry a storage of 8 000 cu. yd. of crushed stone was accumulated during the latter part of the job, when the concreting slacked up at the dam. This stone was stored beside the main line of the quarry branch, being dumped from 7-yd. cars over the side of a 10-ft. embankment. Storing this material at that place permitted the quarry to shut down, thus getting rid of a large overhead expense some time before the concreting at the

dam was finished. This material was afterward loaded by a locomotive crane operating a ½-yd. clam-shell bucket. A maximum quantity of 8 400 cu. yd. of sand was in storage on December 14th, 1913, and approximately 2 000 cu. yd. of Elmore gravel, and 2 800 cu. yd. of washed gravel. These quantities of materials were put into storage primarily in order to avoid hauling over the railroad any more material than was absolutely necessary after January 1st, 1914, the rainy season generally starting about then and giving a great deal of trouble from soft track, derailments, etc.

Cement Storage.—Cement was stored in two warehouses, the main one being in the Lock 12 yard, and having a capacity of 15 000 bbl. This building was absolutely damp-proof, and the cement stored there was well preserved. The other warehouse, accommodating about 2 000 bbl., was built at the mixers. This storage fluctuated considerably, as it was used simply to insure a supply of cement at the mixers at all times. Most of the cement used at the mixers was unloaded there directly from cars and was not kept in storage.

Sand.—So much loam and foreign matter was contained in certain sections of the sand pit that it became necessary to place an inspector there. He sampled the sand from fixed positions in the cars and made the ordinary rough test of mixing it with water in large test tubes and allowing the material to settle after being thoroughly shaken up. The coarse sand settling to the bottom was measured, and the percentage of clay or loam resting on its surface was determined. Cars containing more than an average of 10% of clay or loam, as determined by this method, were not accepted. This percentage was greater than is ordinarily allowed, but there were times when no cleaner sand could be obtained, and many carloads were rejected. The concrete obtained with the sand was very dense and of excellent quality. A very close watch was also kept on foreign crushed stone, as some of it was dirty; if it was bad, it was rejected, by an inspector at Ocampo, before being brought to the dam.

Watch was also kept and inspection made of incoming materials at the dam. The engineers in charge on the dam made regular trips during their respective shifts to the bins and the mixers, and kept close watch on the character of the materials running.

A good deal of trouble was caused by using washed sand from foreign pits by itself; being very coarse, it would not hold the cement

or water, and would not dump out of the buckets, thus causing considerable delay at times. The principal remedy was to dump cars of fine sand containing some loam alternately with the coarse sand, mixing it as much as possible in this manner. About 30% of this coarse sand was retained by a ¼-in. screen.

A series of tests was run on the Elmore gravel, and also on the washed gravel, to determine its fineness; 50% of the washed gravel would pass a ½-in. screen, and 55% of the Elmore run-of-pit gravel would pass a ⅛-in. screen.

The quantities of the various materials were determined both by measurement and by weight. All materials coming through Ocampo were weighed on a standard track scale installed by the Power Company. One hundred cars of material of each class were weighed and also measured, and the weight per cubic yard was thus determined. This factor was then used on all subsequent receipts. All quarry-crushed stone was measured in cars at the quarry by the inspector. All cyclopean stone was measured on cars by the yard clerk at Lock 12.

Section C—The Prosecution of the Work.

Railroad.—Owing to the site of the dam being 12 miles from the nearest railroad, one of the first problems to be solved was that of building a construction railroad. Time was very limited in which to construct this railroad to the site of the dam, as it was August when it was decided to start the work at Lock 12, and a railroad, under the contract, was to be completed to the dam by November 20th, 1912. As a matter of interest, plant was delivered there on November 26th. This short time allowance was practically the governing feature in the selection of the route adopted.

An old abandoned lumber road, known as the Clear Creek Railroad, extended from Ocampo, a point on the Louisville and Nashville Railroad 39 miles from Birmingham (Fig. 3), toward the dam, a distance of 17 miles. By extending this road 5 miles, the site of the dam was reached, making a total length of 22 miles. Surveys and investigations indicated that this would be the best route by which to get a railroad to the dam in at least 60 days. It was necessary to rebuild about 45 trestles on the old road and to re-tie it. The rails were still on the original ties, never having been taken up.

An inspection of Fig. 3 at once brings up the question: Why was the line not brought down from Ellison Quarry along Yellow Leaf Creek to the dam site, thus reducing the haul from the quarries materially? The answer is that, at the time Zion and Ellison Quarries were selected, the main line had been extended nearly to the dam, and about 80% of the work on the extension was done. If the quarries had not been at Zion and Ellison, the natural route for the line would have been as built.

In August the Power Company started a force of men from Ocampo to rebuild the old line, and a large grading outfit started to grade at the end of this line toward the dam. The work was completed, and steel was laid to the dam by November 26th, when carloads of plant were moved in. The roadbed, however, was still in a very bad condition, and 3 months more were spent with heavy forces re-tieing, surfacing, and opening up the old drainage channels which had become clogged. A steam shovel was put in, and the last 12 miles of the line on the dam end was ballasted, with shale taken out by the shovel and with crushed stone from the quarry. The first 10 miles of the road ran through a very rough hilly country, and the line was exceedingly crooked and full of heavy grades, though the roadbed was good and needed no ballast. On this section the maximum curve was 35° on a 2½% grade, the maximum grade being 4 per cent. On account of these physical conditions, Shay engines were used entirely on this division, five in all being purchased or rented.

The operation of the railroad was quite a problem in itself. In the height of the season more than 250 men were employed on it alone, and on some days more than 100 trains of all classes were operated. The road was divided into two distinct divisions, the first 10 miles being the Shay Division, using the Shay engines only, and the last 12 miles, including the Quarry Branch, operated by rod engines. During the period of greatest activity, outside of switching service, five Shay engines and six rod engines were used. Operating out of Ocampo, a 40-ton Shay engine could haul only 2 cars of sand or 3 cars of cement to a train. On the rod-engine division, 5- and 6-car trains were hauled with 60-ton engines.

On the rod-engine division, 8 miles from the dam, a branch line ran down to the quarries, a distance of 2 or 3 miles, and the heaviest movement was between this junction and the dam. Railroad head-

quarters were established at this point. A regular camp, similar in character to all the others, was built, shops were put up to take care of the rod engines, and a commissary was maintained. The superintendent, master mechanic, car repairers, and all rod division trainmen, hostlers, shopmen, etc., lived there. All Shay division trainmen, machinists, etc., lived at Ocampo, where there was a smaller camp; a well-equipped shop had to be maintained at this point, also, to take care of the Shay engines.

The Shay engines gave a great deal of trouble, their maintenance costs were high, and this division of the railroad was the most troublesome to operate. The use of Shay engines here was compulsory, as no other type could work on the grades and curves of the first 10 miles of the line. In view of the experience gained here, their use should be avoided, if possible. If a new line is built, it should be laid out for the use of rod engines throughout, and for heavy traffic. In the original road at this place 58¼-lb. steel rails were used, but were too light. The writers would recommend nothing lighter than 75-lb. steel where traffic is handled directly in the original cars from a connecting railroad, because, in such cases, net loads of 50 and 60 tons will have to be taken care of in modern cars of 100 000 lb. capacity. The tracks should be well ballasted and the roadbed should be standard in every respect.

The time element entered largely into the selection of the railroad as used, making it almost compulsory. Had there been more time, it is quite probable that an entirely new and independent line would have been built from some near point on the Louisville and Nashville Railroad to the dam. The building of such a line, however, would have delayed the work at the dam from 60 to 90 days, and it was not considered good policy to do this, with the short time available in which to comply with Government requirements as to the completion of the dam.

Stream Control.—The first essential feature of the work that had to be studied and carefully worked out in detail was that of the control of the river. All indications and records of the behavior of the Coosa for 15 years previous indicated that this in itself would be no small part of the problem, and that its solution would have a most important bearing on the progress of the work. All the Government records for a period of 15 years previous to 1913 indicated a

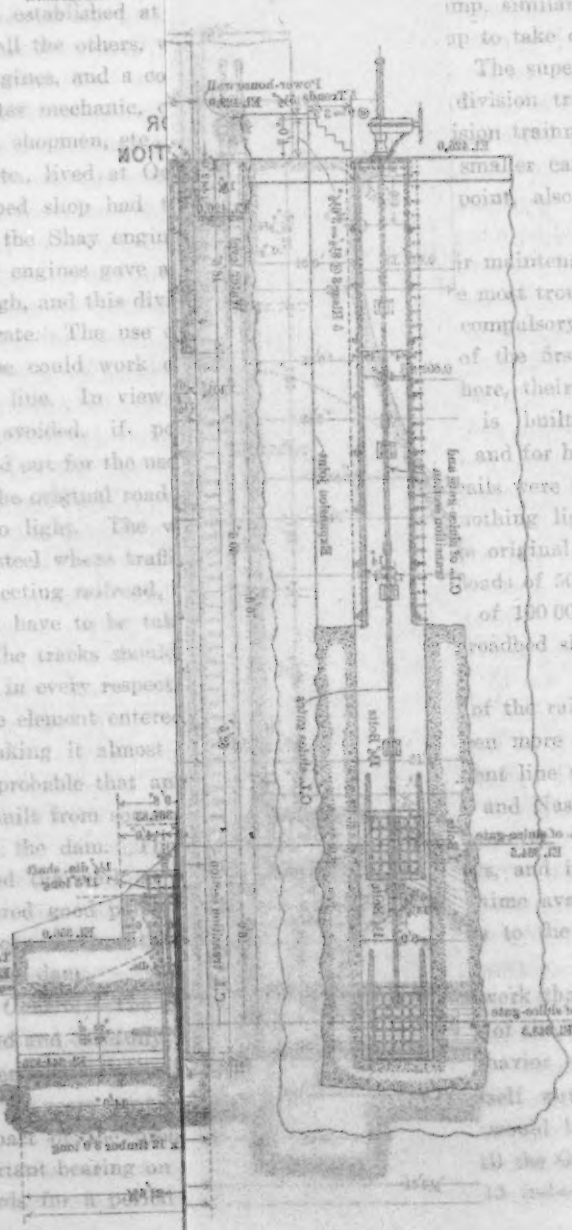
UNIV. OF MICH.



minimum flow of about 2 000 sec-ft. in the dry season and from 90 000 to 100 000 sec-ft. in the rainy season. Table 2 contains these records. It was necessary, therefore, to determine just how great a flood should be taken care of without flooding Coffer No. 1. It was not desired to build a coffer-dam to withstand the maximum flood, but, at the same time, it was considered necessary to build one of such height as to withstand an average high flood during high-water season. This was fixed at about 70 000 sec-ft., and calculations indicated that a dam, obstructing practically two-thirds of the stream, with its top at Elevation 360 would pass that quantity before flooding. The discharges, as determined by gauging the river below later, showed that with the river at this elevation above the dam, 85 000 sec-ft. were passing. It was anticipated that Coffer No. 1 would be flooded, and this happened three times during the high-water period. The first coffer was built as determined, and the dam was concreted. In the section of the dam concreted, however, three permanent culverts were left in the waste-way section, as shown on Plate XXVI, to fulfill a Government requirement calling for the passage of 4 200 sec-ft., with the water at Elevation 406. In the spillway section of the dam, there were left eleven tunnels, each 15 ft. wide and 16 ft. high, capable of passing 20 000 sec-ft. at Elevation 358, which was the elevation of the top of Coffer No. 2. From the top of each of these tunnels, two shafts ran upward through the spillway section and were used for filling them when the gates in front of them were closed. When the work inside Coffer No. 1 was above Elevation 360, this coffer was cut out and the river was turned through the eleven 15-ft. openings. Coffer No. 2 was then completed, and the work in it was finished. The work in Coffer No. 2, it was anticipated, would be accomplished during the low-water summer season, and the eleven openings would be ample to take care of any quantity up to 15 000 sec-ft., without flooding the coffer. The charts of previous years showed one or two flashy floods of from 15 000 to 25 000 sec-ft. during this average period. There was one flood of this character before the work inside the coffer was finished, water coming over into Coffer No. 2, delaying a portion of the work therein about a week, in October, 1913.

In the section of the dam constructed inside Coffer No. 2, ten 8 by 12-ft. openings were left, their bottom elevations being 357,

which was approximately 4 ft. below the top of the large openings left in Section No. 1. These openings were left as a positive safeguard to the power-house end of the work. This portion of the work was much slower than that on the dam, and it was feared that it would hang over until January, which was a very doubtful season, and a month in which a great deal of water might be expected. It was feared that, with only the eleven 15-ft. openings, a heavy and protracted flood would back up the river and there might be a rise sufficiently high to flood out completely the power-house work. The ten 8 by 12-ft. openings would have prevented this and, at the same time, helped to draw down the river more rapidly, if it rose to a considerable height.

Two types of gates were used to close these openings, a detailed description of which is given elsewhere. Figs. 15 and 16 give an idea of how these openings were arranged and closed.

Coffer-dams.—The construction of Coffer-dam No. 1 was begun on September 11th, 1912. It was composed of cribs 20 ft. square, roughly divided into two compartments; an 8-ft. compartment on the outside for clay and loam, and a 12-ft. compartment on the inside for rock. The cribs were built on the shore, launched, towed to their places, and sunk. After getting about 300 ft. out from shore, it was found necessary, on account of the increasing current, to stretch a ¾-in. wire rope across the river, by which the cribs were trolleyed out and placed. Before building a crib, soundings were taken, and the bottom timbers of the crib to be placed at that point were framed to conform as closely as possible to the shape of the bottom of the river. The coffer-dam was built of separate cribs to about Elevation 353. The joints in the timbers from that elevation to the top were then broken in the center of the cribs so as to make it as strong and as near one unit as possible. Sheeting, consisting of two thicknesses of 2-in. plank with lapped joints, was then placed on the outside of the cribs, and a toe-fill of sand, gravel, and loam, with a slope of about 1:1, was placed around the complete dam on the outside. Rock for filling and weighting the cribs of Coffer No. 1 was secured from a slate quarry about 200 ft. up stream from the dam, on the west bank of the river. Owing to the extreme swiftness of the current, the east or river end of Coffer No. 1, running up stream and down

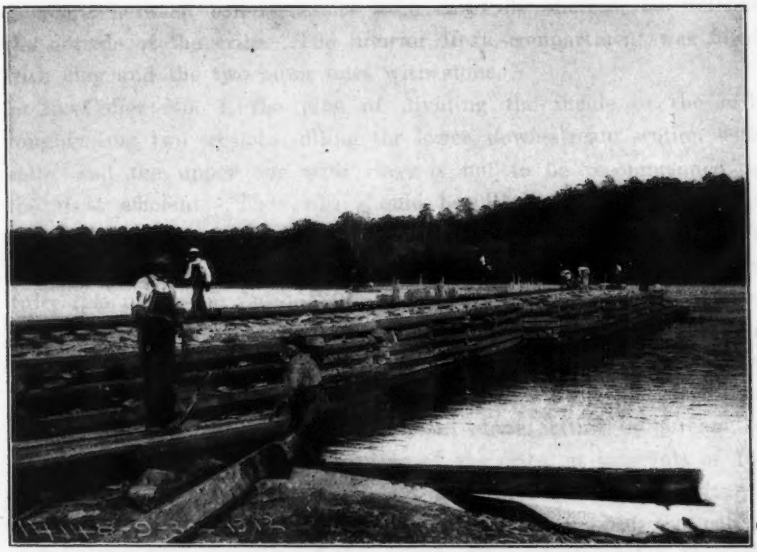


FIG. 25.—COFFER-DAM NO. 1, SHORTLY AFTER INAUGURATION OF WORK AT LOCK NO. 12.

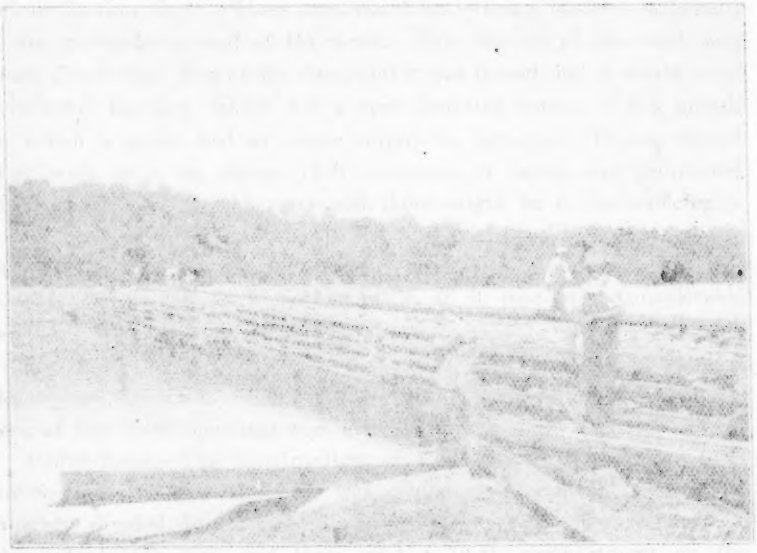
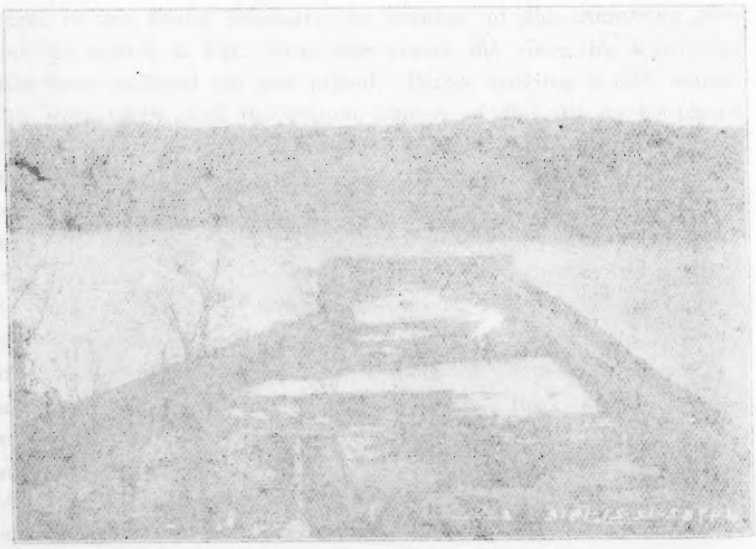
FIG. 26.—COFFER-DAM NO. 1 COMPLETED. DRILLING OF FOUNDATION STARTED.





stream, was made 30 ft. wide with three 10-ft. compartments. All divisions between compartments were carefully sheeted, as well as the outside of the cribs. The interior 10-ft. compartment was filled with clay and the two outer ones with stone.

In Coffer No. 1, the plan of dividing the inside of the crib roughly into two sections, filling the lower, down-stream section with stone and the upper one with clay, is not to be recommended as the most efficient. The cribs should be filled entirely with stone, and all stoppage of leakage should be made with a substantial earth or clay toe-fill on the up-stream side, care being taken to sheet carefully this up-stream face. When the toe-fill has been properly made, if there is much current, a 2- or 3-ft. layer of rough rip-rapping should be dumped on the outside to protect it from wash. If there is much wash of the earth toe-fill while it is being placed, it can be stopped effectively by building small stone jetties up stream 30 or 40 ft., at right angles to the line of the cribs, at intervals of 150 ft. or more. This scheme was used here with excellent results.

In the case in question, the first flood that topped the coffers took out a large portion of this inside fill, and the space formerly occupied by the earth had to be refilled with stone. It was also found that this interior fill was not effective as a leak stopper unless it was made like the outer river end, that is, in a tightly sheeted interior chamber which absolutely prevented any wash through it.

The first timber used in making the coffer-dam was squared on four sides, but, later, timber squared on two sides was used, which decreased the time of handling and expense at the saw-mills. All coffer-dam timber was hauled from the mills to the dam—about ½ mile—by teams. On Figs. 25 and 26 is shown the beginning of construction of this coffer and its completion. Fig. 27 shows typical sections of the various coffer-dams.

Pumps were started on December 3d, 1912, but numerous leaks developed under the down-stream coffer, and the pumps were shut down until the toe-fill could be fully placed along the south section. A portion of the river bed was finally unwatered by December 13th, 1912. Coffer No. 1 was entirely completed by December 21st, its total length being 1 640 ft. It contained 525 000 ft. b.m. of timber, and took a little more than 3 months to complete. The

filling for this coffer, as well as for all others, was carried in 1½-yd. cars, which were filled by hand, from quarries on each bank of the river, with stone and earth from earth pits in the bottom, and hauled in trains of 4 cars each, by a mule, out on the coffer as far as it was completed. This method proved satisfactory, and no great trouble was experienced.

On May 20th, 1913, a coffer-dam, 10 ft. wide, was started below Coffer No. 1 to encircle the tail-race excavation (see Figs. 23 and 27). As the water was very low at this time, it was not necessary

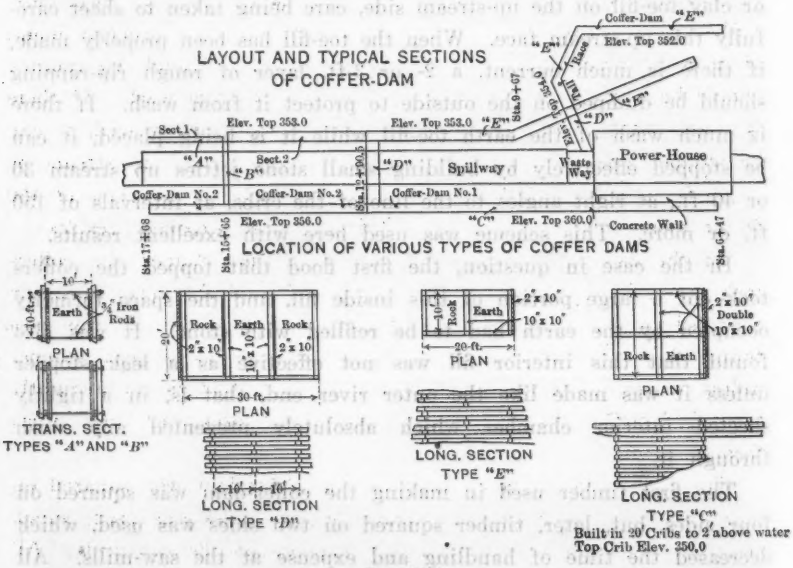


FIG. 27.

to build cribs on the shore, and they were constructed in place, the water being about 4 ft. deep. The average height of this coffer was 6 ft., the elevation of the top being 350.5 and its length 655 ft.

Coffer No. 2 was begun on June 17th, 1913, and the up-stream side was built of cribs, of the same size and in the same manner, as Coffer No. 1. A false deck was built above the water on this coffer and loaded with stone, allowing the water to run through the cribs until the up-stream section was practically completed and connection made with Coffer No. 1, when it was filled entirely with stone. This was done to keep the current as slow as possible to

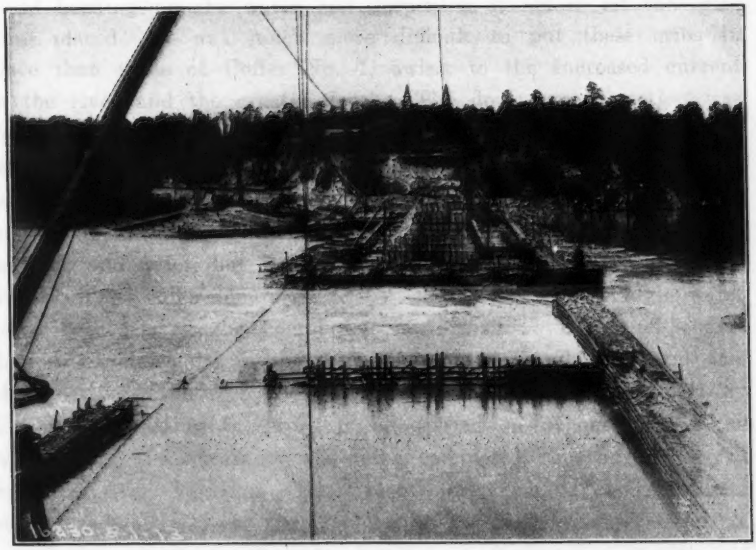

FIG. 28.—SECOND COFFER-DAM, SHOWING CONSTRUCTION OF LIGHT PARTITION RIBS UNDER WAY.

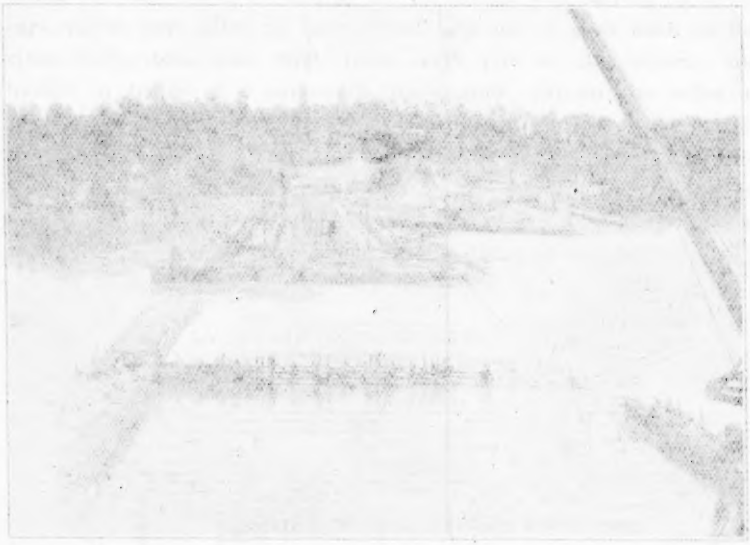
FIG. 29.—CUT-OFF TRENCH PARTLY FILLED WITH CONCRETE, SHOWING TYPE OF ROCK FOUNDATIONS.



avoid backing up the water and deepening it before all the cribs were placed. It was much more difficult to put these cribs in place than those of Coffer No. 1, owing to the increased current in the river and the greater depth. The down-stream section was built by using two 10 by 10-in. uprights with two 10 by 10-in. wales on the inside and 2-in. sheeting nailed on the inside of the wales, with only a loam fill. This makes a very cheap and quickly constructed coffer-dam, where there is not much head and the water is slack and quiet, but it is not very stable, and is easily washed away. This coffer-dam was partly constructed when high water came and delayed the completion and closure. A cut-off coffer-dam was constructed in the same manner as the down-stream one, about half-way between the shore and Coffer No. 1, as shown by Fig. 28, permitting the work to be carried on in one-half of the coffer, while the remainder was being completed, thus advancing the work by about 10 days. The average elevation of the up-stream side of Coffer No. 2 was 354, and that of the down-stream side, 351.5.

Closure of the north line of cribs of Coffer No. 2 with old Coffer No. 1 was made on August 20th, 1913. The closure in the south line was made about August 27th, 1913.

The total length of all the coffer-dams was 3 423 ft., and the total quantity of lumber and timber used was 898 984 ft. b.m.

Excavation in Dam and Power-House Foundations.—In general, the rock throughout all the foundation of the dam and power-house was a hard, blue, thin-bedded slate with numerous quartz seams running through it. Its outcrop crossed the axis of the dam at an angle of about 45° and dipped down stream, thus affording additional security from leakage and sliding. The general rough character of this bottom is shown by Fig. 29. Occasional soft streaks, from 6 to 8 ft. deep and from 25 to 75 ft. wide, were encountered, and these were worked entirely out, down to the hard blue slate. All rock excavation was drilled with Ingersoll, E 24 drills, operated by air. These drills made 2-in. holes, having a depth which varied according to the character of the rock. This feature was watched carefully by the engineers on the dam, and the depth of hole to be drilled in various sections was given to the drill foreman; the quantity of powder to be used was also specified. The quantity of dynamite varied from 1½ to 6 sticks of 40% Red Cross du Pont

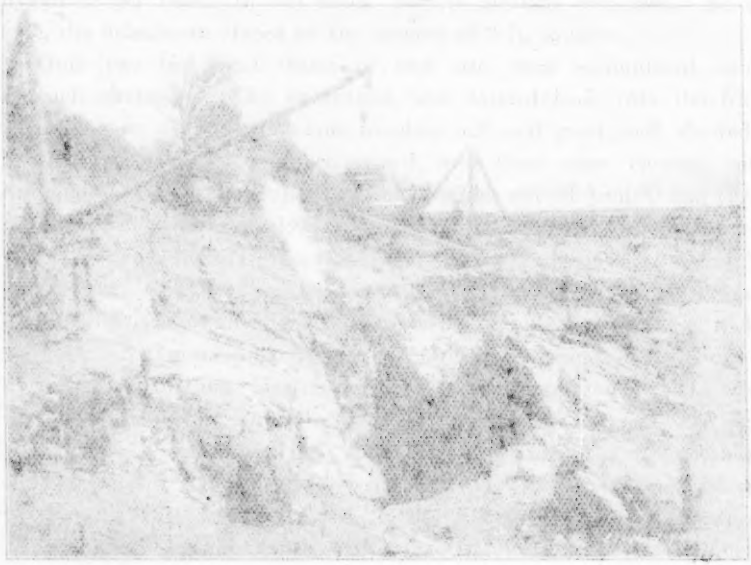
dynamite per hole. In wet holes, Forcite gelatine was used. As a rule, the holes were placed on the corners of 3-ft. squares.

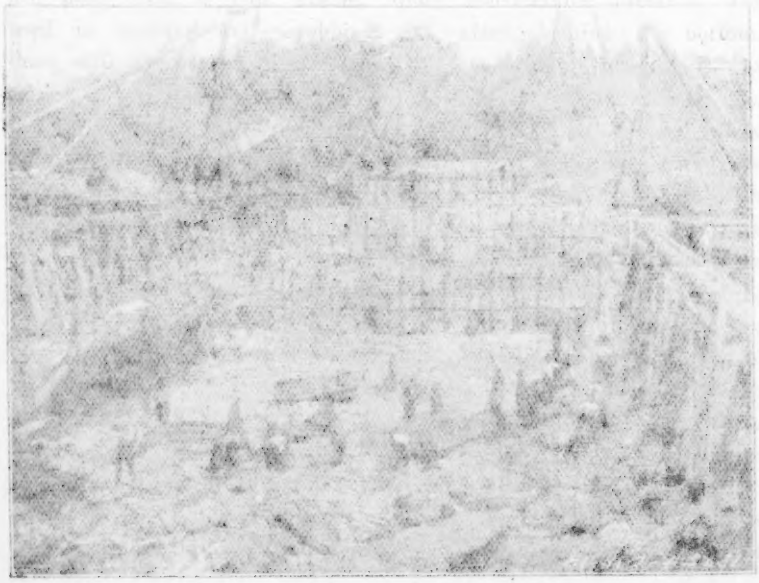
Only two bad mud seams of any size were encountered, one in each abutment. The excavation was carried back into the hill in each case until these seams pinched out and good rock showed. Some small seams were encountered, and these were cleaned out thoroughly and grouted under pressure. The cut-off trench was carried from 6 to 15 ft. below the general level of the excavated bottom; its excavation is described under the heading "Channeling." No differences in the character of the rock in the "cut-off" trench from that in the bottom, already described, were found, except that the rock was somewhat more compact in the bottom of the cut-off trench.

After the drilling, blasting, and excavation of the materials was completed, and the bottom was fairly clean and compact looking, a gang of 20 men was put in on a 75-ft. section and generally worked there 2 days, barring, wedging, and picking the surface of the work. This was continued until all loose slabs of slate were removed, and then scrubbing, washing, and cleaning were continued until the foundation was absolutely clean and free from all loose materials. Wire brooms were used all over the bottom, and a 2-in. fire hose, with a ½-in. nozzle, under considerable pressure, was used in washing and scrubbing. If, after cleaning the bottom, there still appeared to be pockets or layers of soft material, it was again drilled, shot, and excavated, and then finally cleaned up. Wherever leaks of any consequence occurred (which were generally low down in the "cut-off" trench), a cone of spalls and mortar was built, completely enclosing the leak, the water being led out of a 1½-in. pipe from the bottom of the cone and another pipe rising out of its top. When the cone had set, the drain from the side was plugged and the water was allowed to rise in the vertical pipe. This pipe was brought up until some 15 or 20 ft. of concrete lay over the leak, and then it was grouted under pressure up to 50 lb. Where several bad leaks were encountered, a well was formed in a suitable place in the "cut-off" trench, and all the surrounding leaks were led to it through 1½ and 2-in. pipes. A pump was set up nearby to keep the water lowered in this well until the concrete was well set. The well was brought up to such height as was necessary to bring the water level to a stand, then it was pumped

FIG. 30.—DEEP GRAVEL POCKET ENCOUNTERED IN FOUNDATION, BETWEEN UNITS NOS. 1 AND 2 OF POWER-HOUSE.

FIG. 31.—GENERAL VIEW, SHOWING METHOD OF HANDLING WORK AND TYPE OF WALL FORMS USED.





down, the forms and dirt were cleaned out of it, and grout pipes were brought up from the drains leading into the wall, and then filled with concrete. After the concrete had set, the leaks were grouted back, under pressure, through the original drain pipes. There were no serious leaks in any portion of the work.

The rock under the power-house was slightly heavier and more dense than in other portions of the foundations, but at the west end, between Units 1 and 2, and partly under Unit 1, a large cavity filled with sand, gravel, and slate boulders was found. This cavity extended the full width of the power-house up and down stream, and was about 50 ft. wide on top, narrowing to about 15 ft. at the bottom. It was wedge-shaped, with the small end down stream. Fig. 30 is a view of this hole. The lowest part of the hole was at Elevation 291.0, or 35 ft. below the bottom of the draft-tubes. The hole itself, the writers believe, was of the nature of an old "geological mill," and was worn out by the whirling around of gravel and sand in pot-holes, these pot-holes wearing eventually into each other. The hole was cleaned to the bottom, as a dentist cleans a cavity in a tooth, and then filled with concrete. The hole extended both up and down stream beyond the limits of the excavation, and may have been of considerable length. Two derricks were used in excavating it, handling 1½-yd. cars from the hole to a narrow-gauge track, the material excavated being used for a toe-fill on the outside of the coffer-dam. After solid rock was reached at the bottom, 16-ft. holes were drilled in various places to make sure that there were no caverns below, but the rock drilled solid and clean. The 2 200 cu. yd. of concrete necessary to fill this hole to the general level of the surrounding bottom was poured through a chute, which was built directly from the mixer.

The following quantities were excavated:

Dam	Earth	3 379 cu. yd.
	Rock	15 442 " "
Power-house	Earth	8 572 " "
	Rock	11 818 " "
Tail-race	Earth	8 029 " "
	Rock	11 245 " "
Total		54 845 cu. yd.

Excavation was started on the dam and power-house foundations on December 17th, 1912, and completed on October 20th, 1913.

Channeling the Cut-Off Trench.—A cut-off trench, 10 ft. wide, from 6 to 15 ft. below the general bottom of the dam, extending under both the dam and power-house, and well keyed into both banks of the river, was cut. Two channelers were used for both sides of a large portion of this trench.

Time was lost at the beginning of the work in starting these channelers, and it was seen that they would have to be supplemented in order that the excavation of the trench might keep up with that of the general bottom, and be ahead of the concreting. Two quarry bars were purchased and two Ingersoll, E 24 drills were set up on each, channeling in the power-house foundations. These drills put down holes 6 in. apart on the line of the trench. This method was not satisfactory, as the rock was badly shattered in blasting and the trench had to be carried much deeper than was necessary in order to get below the shattered rock. The channelers gave a clean cut and much better job all around, and are far superior to the drill work.

In the abutments only the up-stream face of the abutment was channeled by drills, and no actual cut-off trench was made, the whole excavation into the hill being practically such a trench. The thickness of the channeler steel varied from 1¼ to 2½ in.

Throughout the work on the cut-off trench, 40% Red Cross dynamite was used, with the exception of a few wet holes where 40% Forcite was used.

Disposal of Waste Materials.—At the beginning of the work, before the derricks were in position to handle the excavation, all excavated material was moved by cableways, in 4-yd. steel skips, to 7-yd. dump cars hauled by an engine on the Low-Level Line, the material being used to widen the embankment for that line. This method, however, was very slow and unsatisfactory, it being hard to stop and dump a heavy skip over a 7-yd. car. Later, the skips were landed on flat-cars, taken about 1 000 ft. up the Low-Level Line, on a steep hillside, where a large guy derrick was erected to pick them up and unload them. A large part of the draft-tube excavation in the power-house was made in this way. When the traveling derricks were put in service on the up-stream coffer-dam, a track was laid on the coffer-dam and a dinky locomotive, handling 7-yd. cars, took the excavation from

these derricks. It was lifted out of the bottom in 4-yd., steel skips and dumped on a slanting platform built for the purpose. The material was then dumped over the side of a 10-ft. bank into the river about 200 ft. up stream from the dam. Later, these derricks landed loaded skips on flat cars, handled by a dinky engine and a locomotive crane, on the dump already mentioned, picked them off and wasted them down the bank into the river. Material in the excavation, out of reach of the up-stream derricks, was picked up by those traveling on the down-stream coffer-dam and passed across to the up-stream derricks which, in turn, disposed of it as described.

The tail-race excavation was handled and disposed of in a different way: Two traveling derricks started at the east side of the excavation and backed off toward the west as they cleaned up the excavation. The bottom was drilled, shot, and then placed by hand in 4-yd. skips. These were picked up by the derricks and discharged into 7-yd. dump-cars, which were hauled out of the bottom by a cable operated by a regular hoisting engine, and disposed of down stream about 500 ft. from the side, on an embankment. All the tail-race excavation was made in this manner very quickly and satisfactorily.

In general, the following criticism is offered of the methods used on this work: A cableway is not satisfactory in handling the excavated materials, as it is not only expensive, but slow. A better scheme for the work in Coffer-dam No. 1 would have been a system of standard-gauge tracks laid down from the west bank of the river, through the tail-race, to its extreme east end. The excavation should then have started at that end, backing off toward the west, the spoil, in skips, being lifted with the derricks and discharged into 7-yd. dump-cars, hauled by dinky engines. The power-house excavation could have progressed rapidly, also, at the same time, and both cableways would have been free to erect derricks, get plant and timber out to the job, and handle concrete, thereby advancing the work greatly. The writers are of the opinion that, as a rule, the cableway should be restricted to moving plant, derricks, forms, and general work, and also such concreting as is advantageous to place with it, and that it should not be made the main method for the transportation of all materials on the job, as it was here.

Forms Used for the Dam.—The forms used on the vertical faces of the dam were of the cantilever type, built in sections, 12 ft. long

and 6 ft. high, with upright posts extending 6 ft. below the bottom of the sheeting. Figs. 29 and 31 give a general idea of these forms. All the sheeting was sized and dressed to 1¼ in. in thickness, and all vertical posts were made of two 4 by 8-in. timbers nailed together, with 1-in. blocks between them at the top, middle, and bottom. The waling pieces were 4 by 8-in., or 6 by 8-in., laid flat. These forms were built complete and raised in one piece, from one lift to another, by a 3-ton chain block hung from an **A**-frame, guyed back with form wire to hook-bolts in the concrete. This particular kind of form was not used throughout the job, for, as the work progressed and carpenters became rather scarce, sections of this type were abandoned, and 3 by 6-ft. panels were made in the carpenter shop and simply tacked to the posts. This type was practically the same as the first and was handled more quickly and easily than the forms of heavier section.

The following method was used to hold the forms in place: When a form was completed, ¾-in. bolts, 22 in. long, with an ogee washer on one end, were placed in them, 10 in. below the top, the bolts having a 10-in. hold in the concrete when it was poured around them. Also, when the pour in the form was completed, and while the concrete was still soft, ¾-in. bolts, 12 in. long, with a hook on one end, were set in the concrete opposite each post and about 6 ft. back from the face of the form. When a section form or panel form was raised, it was lifted until the bottom of the sheeting was above the bolts set 10 in. below the top of the previous pour of concrete. The posts were fitted on these bolts which held the form in place, passing through the slot between the two 4 by 8-in. posts. A waling piece at the top of each section was used to wire the form back to the hook-bolts placed in the concrete. Wedges were placed at the bottom of the post to line up the form. The panel forms were handled in the same manner, the loose posts being placed on the bolts previously set in the concrete, and the panels dropped into place behind them and tacked to the posts. As the speed of filling the forms increased, two walings were used instead of one. All expansion joint forms were held in this same way. For the curved section of the dam, on the down-stream face, ribs were cut to the proper radius in the form shop and brought down to the job where sheeting was nailed on them in place at the dam. The ribs for all curved forms were made of two 2 by 8-in. timbers nailed together, with a 1-in. spacing block between them, leaving a 1-in.

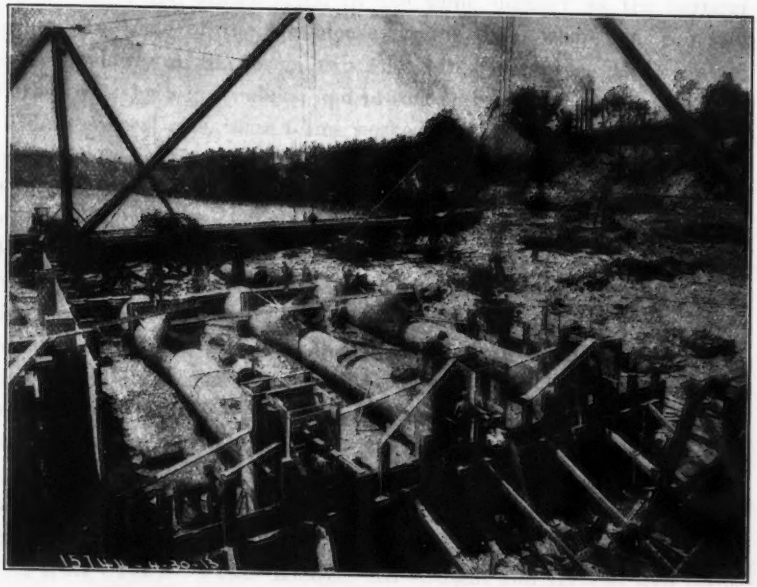


FIG. 32.—FORMS FOR WASTEWAY OR BLOW-OFF CULVERTS.

FIG. 33.—SCROLL CASING FORMS IN PLACE DURING CONCRETING OF FIRST STAGE OF CONSTRUCTION.

slot to catch the anchor-bolts, in the same manner as the vertical forms. In some of the big blocks on the dam, where the concrete came up slowly on the forms, two 2 by 8-in. pieces were used in place of the two 4 by 8-in. timbers, and proved satisfactory.

As a general rule, these forms worked well and were fairly economical of timber. However, it is not the fastest method; after a form is poured, sufficient time has to be allowed for the concrete to set properly and for the bolts to take hold. More rapid work could be done with a form of the same general type, but built up continuously, releasing the bottom sections as the opportunity arose. In building the forms continuously, one could be raised as soon as the carpenters could walk on the concrete, and the next pour could be made from 12 to 24 hours sooner than with the type used. The latter, however, would take considerably more timber, but the speed would be increased, and in a country where timber is very cheap and speed a big consideration, the continuous type might pay. Fig. 32 shows the type of forms used in moulding the wasteway culverts in the section of the dam adjoining the power-house.

Forms Used for Power-House.—All straight and vertical wall forms in the power-house were of the same type, and were handled in exactly the same manner as the dam forms.

All special or curved forms, such as for draft-tubes, scroll casings, and penstocks, were made in the form shop according to detailed drawings furnished by the Company's engineers.

The type of scroll casing used (Fig. 10), was more or less of an innovation, and there was considerable discussion at the beginning of the work as to the practicability of moulding such a complicated opening. The form work, as can be readily seen from Figs. 34, 35, and 36, was highly complicated, and, even when carefully detailed, was difficult of execution in the field, for several reasons: First, the average carpenter foreman is out of his depth on a complicated drawing of this kind; secondly, the setting and lining up of a large form of this character is difficult of execution; thirdly, unless the laying out of the forms is done carefully, they are hard to get out. In the case at Lock 12, the engineers made all the calculations and furnished a sufficient number of detailed drawings to enable the work to be laid out and assembled in the form shop. A competent engineer assisted the carpenter foreman in reading these drawings properly, and laying

out the various parts of the form. The greatest care was exercised in setting up the forms and holding them in place. The work was handled in this manner with no great difficulty, and the final results were excellent.

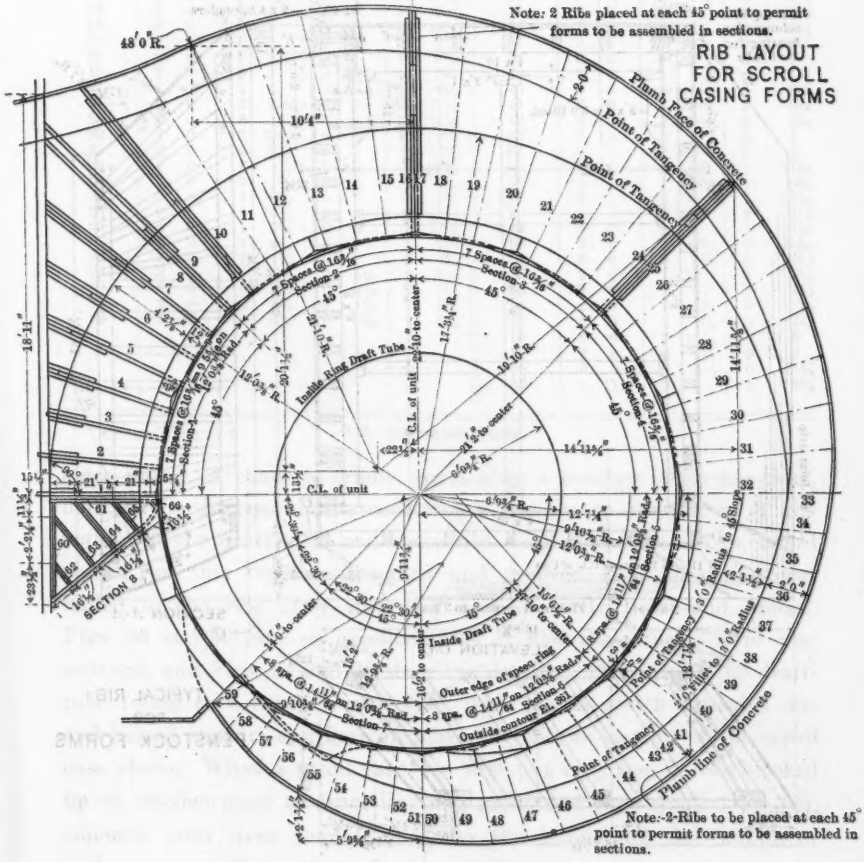

FIG. 35.

In detail, these complicated forms were built as follows: All the ribs of the scroll casings (Figs. 35 and 37), were made according to the drawings furnished, and were then set up in the shop in their proper positions, as laid out, and sheeted with 1-in. material. The

detailed dimensions for the ribs are given in Table 6. On the curved portions, 1 by 1-in. lagging was used, in order that it might bend easily and conform to its intended shape. The whole scroll casing was built in the shop in eight sections in order to facilitate handling

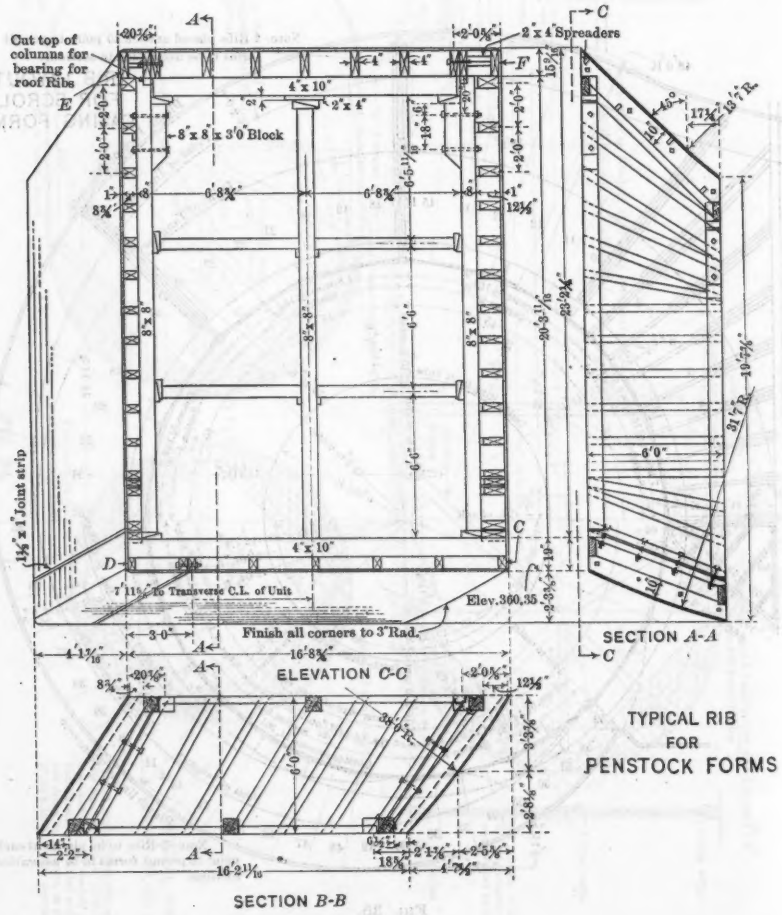

FIG. 36.

and erecting, each section being complete in itself. For the draft-tubes (Figs. 34 and 38), all the ribs were made and fitted together on the form-shop floor; they were then taken down and hauled to the dam and re-assembled on a platform from which a derrick could lift and

place them. A concrete cradle, containing a number of anchor-bolts, had previously been built, conforming exactly to the curve of the bottom of the draft-tube, and these ribs were placed on a 1-in. board resting on this cradle. Tongued and grooved 1-in. sheathing was nailed to the ribs after they had been properly lined and braced. Figs. 33 and 39 give an excellent idea of how these forms were constructed, and Figs. 34 and 38 show the details. The tops of the draft-tube forms were covered with 2 by 6-in. planks which extended out and helped support and keep in place the bottom section of the scroll case above. When a scroll case was first put in place, it was blocked up on wooden posts to exact line and grade and then small 1 by 3-ft. concrete piers were poured up under the joints and the middle of each section. These piers also contained anchor-bolts, and after the concrete of the piers had set, the forms were bolted tightly to them. They were also wired down to hook-bolts set in the concrete below, to keep the form from floating. Penstock forms, Fig. 36, were made in sections, 6 ft. long, in the carpenter shop; they were then knocked down and transported on cars to the dam, where they were re-assembled

out floor, and also all curved ribs for other forms at the carpenter shop, is recommended on similar work. The shop, however, as previously noted, should be much closer to the job than it was on this work. The concrete-cradle method of setting these large forms is recommended as the best and most accurate.

Quarrying Operations, Zion Quarry.—Fig. 24 shows the general layout of the quarry tracks and plant, and the general relation between the various portions of the work. The actual work of clearing and erecting the camp and plant at Zion Quarry was started on November 11th, 1912. On January 20th, 1913, a force was put to work stripping from the toe of the hill, and tripod drills were started. On January 20th, a well drill was also put to work on the side of the hill, drilling the first round of 40-ft. holes; the well-drill outfit was increased later to a total of three. On February 12th, 50 teams were put to work to strip the top of the quarry. On February 16th, 1913, the first large blast was made, and actual quarrying operations were started. The crushers had been started on February 24th, to crush run-of-the-quarry stone for ballast purposes on the railroad and also to get the new plant in good running order by the time materials were needed for concreting at the river. One locomotive was assigned to the quarry service, and did no other work than to spot cars to the derricks in the quarry and to the crushers.

Five steel guy derricks were erected along the face of the hill, on about 100-ft. centers, after the first round of well-drill holes had been shot, the toe of the hill having been previously shot out. These derricks handled 5-yd. steel skips to the points wanted in the quarry, where they were loaded by hand. Stone too large to be lifted by hand and too small for cyclopean masonry was broken with a "skull cracker," which consisted of a cast-iron ball weighing 1 ton and fixed to the hoist line of the derrick by a trigger tripped with a hand line from below. The ball was spotted over a stone carefully, hoisted about 50 ft. and dropped, smashing the stone effectually. Crusher muck was placed in four skips which were loaded by derricks on a flat car. These loaded flat cars were picked up from all the derricks by a locomotive, pulled out, and spotted at the washing platform, and a train of empties was placed at the derricks. After carefully washing all mud from the crusher muck, the cars were spotted to a large timber guy derrick which picked up the skips and dumped them directly into the No. 9 crusher. The dumping device was simply a heavy inclined platform, on which the skip was lowered and prevented from sliding down by a lug under the skip catching a lug on the back of the platform. The skip was held and the contents slid out. After passing through the crushers, the stone was

FIG. 39.—DRAFT-TUBE FORMS UNDER CONSTRUCTION, SHOWING CONCRETE CRADLE ON WHICH THEY WERE SET UP.

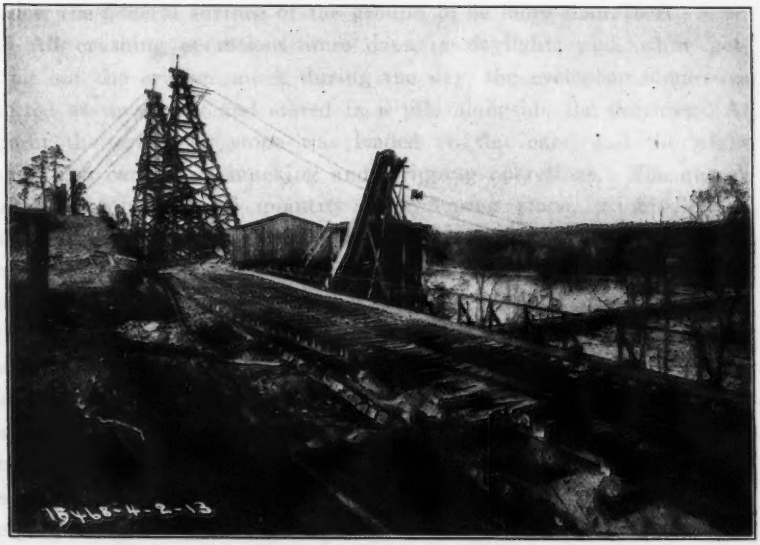

FIG. 40.—END OF HIGH-LEVEL LINE, SHOWING CABLEWAYS, CEMENT WAREHOUSE, AND MIXER BIN.

carried by a belt conveyor to a bin of 1 800-cu. yd. capacity, and drawn from this bin directly into hopper-bottom cars by gravity. (See Fig. 21.)

Well-drills were used for all the heavy work, being augmented in the bottom by tripod drills and Jap hammers. Well-drill holes varied in depth from 40 to 60 ft. These holes were drilled from 15 to 18 ft. back from the face and at about 18 to 20-ft. centers, 4 by 8-in. sticks of Forcite gelatine, 40% dynamite, being used. The largest size of Forcite obtainable was 4 in. in diameter, and the holes originally drilled to 6 in. were reduced to 5¾ in. in order to get the full benefit of the explosive of this size. Only three rounds were taken from the face of the quarry at Zion owing to the heavy over-burden farther in the hill. After they had been cleaned up, about 6 ft. of earth, overlying the rock in a meadow directly in front of the quarry, was stripped back a distance of about 75 ft., and the quarry was then carried vertically downward 60 ft. for a total width of 100 ft. and a length of 450 ft. The seepage from a nearby creek was small and easily taken care of by a No. 6A, 8 by 5 by 13-in., 100-gal. pump. The stone was of excellent quality, and seemed to grow denser with the depth. A well-drill test hole indicated the thickness of the stone below the general surface of the ground to be more than 75 ft.

All crushing operations were done in daylight; and, while getting out the crusher muck during the day, the cyclopean stone was sorted as uncovered and stored in a pile alongside the derricks. At night the cyclopean stone was loaded on flat cars, and the night shift also carried on mucking and stripping operations. The quarry afforded only a small quantity of cyclopean stone, principally on account of the limited space and the necessity for getting out enough crushed stone to keep work going at the dam. It was not possible to take the time to get out the cyclopean stone, because by doing that the crushing would fall behind. In other words, the quarry was such that a sufficient quantity of either crusher muck or cyclopean stone could have been gotten out separately, but not both at the same time. Difficulties and uncertainties in the transportation of coarse aggregates from the outside would not allow that source to be depended on entirely, and reliance had to be put principally on the company's crushers. For these reasons the percentage of cyclopean stone at the dam was much smaller that it would have

been under more favorable circumstances. In this case, the percentage had to be sacrificed to other requirements which were considered more important.

Ellison Quarry.—Ellison Quarry, about 1½ miles east from Zion Quarry, did not prove a success, as stated previously, owing to large clay seams which appeared throughout the rock after shooting. This quarry was worked, however, from March 17th, 1913, when stripping was started, until August 31st, 1913, the same methods of drilling and shooting being used as at Zion Quarry. A locomotive was assigned to its service, as at Zion, and two steel guy derricks were worked. The crusher muck was hauled to the crusher at Zion and unloaded there in the same manner as at Zion Quarry. The stripping at Ellison was done by teams and a steam shovel, there being a heavy overburden against the toe of the hill.

Storage.—Whenever a surplus of crushed stone accumulated in the bins at Zion, it was drawn out into 7-yd. dump cars and stored in a pile alongside a 10-ft. embankment. About 8 000 cu. yd. were stored and afterward picked up by a locomotive crane, operating a ½-yd. clam-shell bucket. By storing materials, the crushing and quarrying operations were carried on continuously, and a shutdown at the dam did not affect the quarries.

Zion Quarry was closed on December 24th, 1913, all the camps were removed, and the plant was shipped out.

Concrete.—As many different classes of material were used in the work, the coarse-aggregate bin, having a capacity of 800 cu. yd., was roughly divided into two sections; all crushed stone was dumped in one end of the bin and all washed gravel and Elmore gravel, consisting of 55% gravel and 45% sand, were dumped in the other end. The sand section of the bin was separated from the coarse-aggregate section by a partition. The crushed stone and gravel were drawn to the conveyor belt at the same time, in about equal proportions, and were elevated into the coarse-aggregate hoppers above the mixers. The sand was drawn by itself and ran into a separate bin, also above the mixers. There was a charging hopper just above the mixers, and all materials were drawn from the bins above into this hopper, where they were properly proportioned.

The mixing of the concrete was watched by an inspector on duty at all times at the mixer plant, and he was constantly in touch with

the chief inspector on the dam, who also with his assistants kept close watch on the concrete coming to the dam.

Three mixtures were used: 1:3:6 in the main body of the dam and the heavy sections of the power-house; 1:2½:5 in the cut-off trench and bottom 2 ft. of the foundation of the dam; and 1:2:4 around the scroll casings, penstocks, and all reinforcing in the power-house. The greater percentage of crushed stone came from Zion Quarry, the remainder being brought from outside quarries and shipped to the dam by rail. In addition to the crushed stone, 31 034 cu. yd. of gravel were used, principally around the complicated curved forms in the power-house and in filling the stream-control openings.

In general, as shown by the analyses of a great many different mixtures used in the work, there was about 10 to 15% too much fine aggregate used. The writers, in view of the results obtained, however, do not consider this a bad feature. There were no honey-combed walls in either the dam or the power-house, and only a few seepage spots appeared in any places except at the vertical expansion joints, the showing in this respect being excellent. When broken off in large chunks, the concrete was dense and had a uniform texture; and when the forms were removed, the outside appearance of all walls was good, no finishing being necessary except in spots where pieces had been broken out by bolts, etc.

Expansion Joints.—At first, expansion joints were placed 108 ft. apart, and after two of them had been started, the distance was cut down to 72 ft. The 108-ft. block proved a little too large to complete satisfactorily as the concrete at one end set before it did at the other. All joints were painted with a heavy coat of hot Barrett pitch. These joints were very effective, as far as could be noted at the end of one winter, and no cracks of any kind developed in the dam.

Handling and Placing the Concrete.—The concrete was dumped from the mixers into 2½-yd. buckets on small cars, or directly into chutes. The cars were hauled by mules to the cableways, two cars being used for each mixer. There were four tracks under the cableways, drawing closely to each other in pairs at the mixers. See Figs. 22 and 40. The buckets were picked up by the cableways and placed at the points needed. No. 1 mixer also dumped directly into a chute. Chutes were used wherever possible to deliver concrete to buckets traveling on small cars operated with a hoisting engine. A large

portion of the power-house concrete was passed through chutes, and the system when properly laid out is most effective. The chutes delivered the concrete to buckets on cars which were taken to the dam, *via* the Low-Level Line and the up-stream coffer, by a dinky locomotive. This method was as effective and rapid as any used on the job. A great deal of the concrete was dumped directly from the cableways, and this method was fairly rapid. However, the maximum 10-hour run with cableways was seldom more than 400 cu. yd. The writers believe that cars and derricks, where it is possible to use them, are more efficient and rapid than cableways. Where narrow forms are to be concreted, the cableway is exceedingly slow and should not be used if any other method can be found.

Cyclopean stones were delivered directly to the derricks on the coffer-dam, and, between buckets of concrete, were set by the derricks. Each stone was carefully washed and cleaned, and, after it was placed, it was carefully shaken with a bar and bedded. In the dam the percentage of cyclopean stone was small, for the reasons mentioned in discussing the quarry operations. The horizontal joints between pours were always left bedded with as many cyclopean stones as possible, in order to get a thorough bond with the next layer.

A total of 6 482 cu. yd. of cyclopean stone was placed in the dam, or 5.1 per cent. In the power-house foundations there were 1 188 cu. yd.

There were two types of chutes on the work. The first was made of No. 12 gauge metal and was 10 in. in diameter. It was of the semicircular type, and was served by a special bottom-dumping car at the mixers. The mixer dumped into the car, and the car was pushed by hand over a hopper to the chute, and dumped into it. This chute was not a success, the main objection being that it was too small. It clogged frequently, and took too many men strung out along it to operate it and keep it clear. The metal was too light and wore out too quickly. This size and type are not recommended for similar work. This chute was abandoned, and a home-made one was built, which gave satisfaction. It consisted of a trough, built in 6 to 8-ft. lengths, with sides about 18-in. high, and well braced; $\frac{1}{8}$-in. sheet iron was rolled in 8-ft. lengths to a half circle, 14 in. in diameter, and fastened into the bottom of the trough, giving a chute with high sides and a rounded bottom. It was of sufficient size, discharged on slopes of 18° rapidly and without clogging, provided the concrete was wet

enough to flow, cost about two-thirds of the price of the first chute, and its life was nearly twice as long. It is to be noted that concrete discharged down a 75 to 100-ft. chute was as good as that which fell only a few feet from the mixer to the bucket, and on dumping the two side by side in the forms no difference could be discerned.

After leaving the mixer platform, the concrete was delivered to a derrick, *via* some one of the routes mentioned, and by it placed in the form. An inspector in the form saw that the concrete was brought up uniformly throughout, no racking being allowed. When it was seen that the form could not be completed in one pour, a temporary saw-tooth bulkhead was put in to prevent thin-edged layers. The inspector saw that all concrete was well worked after being dumped; when it lacked sand, it was worked with shovels and tamped until the mortar had worked its way all through it. All faces against forms were carefully spaded. Two bars were used in bedding the cyclopean stone in the soft concrete.

Before making a new pour on the surfaces of old concrete, they were thoroughly cleaned in the following manner: Two gangs of from 12 to 14 men with foremen, when the work was at its height, were kept cleaning forms only. Whenever possible, the surfaces of the old concrete were cleaned about 12 hours after pouring, while they were still green, all scum mortar and "laitance" remaining on top were carefully picked or shoveled off, and the surface was washed until it was absolutely bright and clean. Great stress was put on this particular feature. Concrete was not allowed to be placed in any form until it was cleaned to the satisfaction of the engineer. After the work got under way, and the amount of cleaning insisted on was fully comprehended by the contractor's superintendent, there was little trouble. Also, after a form had been properly washed and cleaned, a 1:2 mortar was dumped in and swept over the surface with a wire broom just before the concrete was dumped. Leaks through horizontal joints have not appeared in any portion of the dam or power-house, and the writers attribute this to the care exercised in cleaning and working the surfaces of old concrete as described.

Power-House Concrete.—In general, the power-house concrete was poured in the same manner as that for the dam, except that the mixtures varied, as noted elsewhere. Fig. 41 is a general view of the power-house operations on July 2d. The heavy blocks indicated in

the first stage of construction, Fig. 43, were of cyclopean masonry, the remainder being mass masonry. The power-house concreting was prosecuted in four separate stages, and complete details of each of these stages are given on Figs. 43 and 44, and Plates XXVII and XXVIII, respectively. These drawings were followed closely in the field, and were of great assistance. The general plan to be followed was carefully discussed at the beginning of the work, and a line of action definitely decided. Fig. 42 shows the second stage of concreting completed. Fig. 45 shows the second stage completed and the forms for the third stage, that is, the concrete around the penstocks, being placed. In Fig. 46 these forms are shown erected. Fig. 47 shows the down-stream elevation of the power-house foundations, the photograph having been taken from the tail-race. Fig. 48 is a close view of the interior of the draft-tube; the man standing in the center of the opening giving a fair idea of its size at the exit.

General.—On April 12th, the first concrete was poured in Section 1 of the dam, immediately next to the wasteway section. Construction of the wasteway section followed immediately, and then the remainder of the dam in Coffer-dam No. 1, and the heavy foundation blocks in the power-house, shown on Fig. 43 as Stage No. 1.

On May 13th, a night shift on concrete was organized at the dam. On May 26th, concreting in the last block of the dam inside Coffer No. 1 was started, and Fig. 31 shows the general condition at this time. On May 31st concreting was started in Section 6 of the power-house. On June 4th, No. 2 mixer was started and the concreting was begun on the bottom cradles for Draft-Tubes Nos. 5 and 6. On June 13th, the filling of the large natural hole in the foundations under Units 1 and 2 was started. By July 12th the concreting and other work had progressed to such a stage that the water in the river was turned through the tunnels left in Section 1 of the dam. On July 25th, Draft-Tube No. 1 was concreted to grade and ready for the scroll casing. On August 26th, concreting was begun in Coffer No. 2, next to the east abutment, which latter lagged behind on account of a bad mud seam which had to be worked out, and on which concreting was not started until September 22d. On September 5th, the first section of rollway in Coffer No. 1 was reached and poured, this marking the completion to Elevation 406 of a portion of the first section of the dam. On September 27th all the rollway section, inside Coffer

FOURTH STAGE
OF CONSTRUCTION
POWER HOUSE FOUNDATIONS

UNIV. OF MICH.

No. 1 (Fig. 49) reached Elevation 406.0, the crest, and the concrete all along the front of the power-house had reached Elevation 380. On October 13th, the highest run on the concrete was made, being 2 220 cu. yd. for two 10-hour shifts, the day shift alone putting in 1 120 cu. yd. in 10 hours. On October 18th, concreting was started around the first penstock forms, and on October 21st pouring was started on the last section of the dam (No. 9). On November 8th, the concreting of the bottom 4 ft. of the eleven 15-ft. stream-control openings was started. It was completed on November 21st. On November 25th, the dam for the entire length of the spillway was completed to Elevation 406, the crest. On December 20th the power-house concrete reached an elevation of 416 in front, and all the scroll casings, draft-tubes, etc., were ready for the setting of the speed rings. On January 3d, the filling of the stream-control openings was begun, and the work was completed on January 31st. On February 15th, the last wheel casing was set and the last scroll casing poured, completing the operating floor of the power-house to rough grade. On February 28th, the last concrete in the spillway piers was poured, completing the work, and on March 6th, the work of tearing out the mixers was started. From the day that concreting started to the last yard poured, 10 months and 18 days elapsed, and 187 802 cu. yd. of masonry were placed. Fig. 49 shows the finished rollway section before the piers were constructed.

Spillway Piers.—The spillway piers above Elevation 425 were so small in plan and contained so much iron framework that it was very dangerous to dump concrete into them from the cableways. A small derrick was rigged up on a standard flat car—the hoist being operated by air, as usual—for the pouring of these small piers in three 6-ft. lifts each. The cableway delivered concrete to this derrick car. Some 18-in. I-beams, which were bought for the purpose of carrying the traveling gate-operating mechanism between the piers, were used temporarily to span the back of the main piers at Elevation 425, and carry a standard-gauge track for the derrick car. These piers are shown in plan and section on Fig. 19.

Discussion of Methods Used.—In general, as previously stated, the writers do not consider cableways as the most satisfactory method of handling concrete, in view of the experience gained on this job. The system of belt conveyors and elevators for concrete materials is one to be avoided, if possible and if space permits, as a fruitful source

of delay. There was one delay of a week on this work, due to a broken elevator belt, and it was expensive. A gravity plant should be built, if it is possible to lay it out. Handling concrete by buckets on flat cars, with dinky locomotives to the derricks, is preferable to the cableway.

The plant, as laid out and used, was effective and, in 1 month, more than 35 000 cu. yd. of concrete were handled with it, but the writers believe that a gravity plant would have been an improvement and more effective. The point which it is desired to illustrate is that a gravity plant should be carefully sought first, and that cableways should not be made the main method of concrete transportation.

Reinforcement in the Power-House.—Complete and detailed drawings were furnished for the correct cutting, placing, and setting of all reinforcement. All curved rods were laid out on a large platform near the tail-race below the power-house, and there bent with a bender to the curves shown on the drawings. All stirrups, etc., were also made there.

Spacing rods were used, to which the regular reinforcing rods were wired. Large nails were driven into the forms, and the rods were wired to them in order to keep them at the proper distance from the forms. In some cases suspended frames were used to hold the rods in exact position until they were concreted. In all cases particular care was taken to keep the rods the proper distance from the forms and properly spaced. All concrete poured around the reinforcement was mixed in the proportion of 1:2:4.

Completing the Work.

Final Closing.—When all concreting in the dam had been finished, except the stream-control openings, and all piers had been concreted to Elevation 417 on the spillway, and the concreting on the power-house and west abutment to Elevation 420, it was deemed safe to close the gates. Fig. 16 shows these gates hung and ready to close. Previous to the closing, when it was seen that the work was reasonably safe, the west eleven 15-ft. openings in Section 1 of the dam were blocked off by placing wooden gates about 7 ft. high in front of them, one at a time, and a concrete wall, 4 ft. high and 6 ft. thick, was placed next to the bulkhead. This small wall was built first to control the leakage that came through these 7-ft. bulkheads, the water coming

through being collected in an interior box sump in the concrete and led through the wall down stream in pipes which were afterward grouted under pressure. The main part of the opening was then filled to the same height throughout as this front wall, no trouble from leakage being experienced. Each of these eleven openings was treated in the manner described, except that on the five westerly openings, which were built primarily for a stop-log gate, the permanent stop-logs intended for them were dropped into the bottom 7 ft. of the guides and left in. The bulkheads in the remaining six openings were removed after the concrete had set, in order to give a smooth clean sill for the flap-gate to butt against. This work was started on November 8th, 1913, finished on November 24th, 1913, and served two good purposes. It was done primarily as a precautionary measure; the bottom of these tunnels was very close to the natural bed of the river, from 12 to 18-in. on most of them, and with such a small sill for gates of the flap type to strike against, there was a chance for a stone or sunken timber to lodge against it at the time of closing and give a lot of trouble by preventing the gates from seating properly. With this additional 4 ft., the bottom of each tunnel was brought well above the bottom of the river, and also well above the tail-water elevation. There were two gates to each opening, and of the eleven openings, five were of the stop-log type, shown by Fig. 15, and six were of the flap-gate type, Fig. 16. When all these eleven openings had been filled with from 4 to 6 ft. of concrete as described, the ten smaller 8 by 12-ft. gates, which were of the flap type, were hung and securely closed on December 21st, 1913, and caulked around the outside. No water was running through these openings at the time, their bottoms being only 4 ft. below the tops of the large openings. The closing of these gates was a very simple and easy matter, and they were caulked and inspected from the upper side. On December 21st also, five of the larger openings were closed with the ten stop-log gates. The closing of these gates was easily accomplished and did not raise the water very much, as only a small quantity was running through this particular set, the water stage being very low. These gates were then securely wedged and caulked on the outside, up-stream face, and the filling of the tunnels was started. Next, a light template of the larger type of flap-gates still to be closed was made, and each of the openings was carefully checked with this template to be sure that there were absolutely no obstructions to the closing of the gates.

and that nothing of any kind would foul them while they were being lowered. This check was made several times and just previous to the closing.

Owing to the non-delivery of the penstock steel gates by the manufacturers, it was deemed necessary at this time to drop stop-log gates in front of each penstock opening, there being six penstocks with two gates each. As the time was very short and the weather was threatening, it was not possible to secure timbers large enough to withstand a maximum head, consequently, the logs were dropped into the gate grooves and reinforced by four 18-in. I-beams. Later, logs of the proper size were dropped into the grooves regularly provided, the I-beams and logs were removed, and the steel gates put in. The I-beams were those bought for carrying the spillway operating mechanism from pier to pier. All these stop-logs were in and properly bolted and caulked on December 27th. On December 28th, at 7 A. M., the large flap-gates remaining were lowered to a horizontal position, clearing the water by about 2 ft. and rigged up so that by attaching a loose line on one side of the cables holding it above and cutting another loop the gate would fall, but the cable would be held by the loose line and not catch under the gate as it swung shut. On December 27th, rain commenced, and the river, which had been rising gradually all the while, started to rise rapidly, and it was decided to close the remaining gates at once, everything else being in readiness. The gates were closed in the order and at the times shown in the following:

Gate No.	Time closed.
*12	11:20 A. M.
11	1:10 P. M.
10	1:13 "
9	1:18 "
8	1:22 "
7	1:26 "
6	1:28 "
5	1:47 "
4	1:51 "
3	1:54 "
2	1:57 "
1	2:00 "

* Gate No. 12 was first lowered in order to try out the method. The closing of the dam really started with Gate No. 11.

Each gate, after being cut loose, followed three distinct motions: First, a rapid fall of 2 ft. until it struck the water; second, a very slow swinging in with the current until within 3 ft. of closing; and third, a quick, abrupt slam against the concrete face of the wall. The leakage was very small after closing, and was taken care of as described later.

Before the final closure was made, all the gates in the wasteway section were examined carefully, and raised and lowered to test them out in the dry. Plate XXVI shows this wasteway section. Two sets of these gates were left open, and water passed through them during the period of filling the reservoir and for some time afterward, serving to hold the water on the crest of the spillway a little lower while the tunnels were being finally concreted. The water in the reservoir rose with fair rapidity, due to heavy rains, and flowed over the crest of the dam at 9 A. M. of January 1st, 1914. During the period of filling, a careful watch was kept of the river bed below the dam and in the vicinity of the dam itself for any indications of leaks or springs. None whatever was seen, and the dam and rock were absolutely tight.

Concreting the Openings.—In order finally to fill the openings through the dam, the water pouring over the crest had to be diverted and kept out while the work was being done. This was accomplished by building six gates, 3 ft. high and 30 ft. long, reinforced on the back with hog rods, and dropping them into the gate slots provided for the spillway gates. There was only a depth of about 18 in. of water over the crest at this time. All leakage under these gates was stopped by dumping clay and cinder just outside of them, their seats being about 3 ft. from the front face of the dam. It was then necessary to take care of leakage through the openings below and devise a scheme for filling them effectually. The leakage was taken care of in the following manner: A water-tight bulkhead was built about 8 in. back from the inside face of the final closure gate, and a sufficient number of drainage pipes was run from this bulkhead to the down-stream face of the dam to take care of all the water, the leakage being taken care of in most openings by from two to four 3-in. pipes. These pipes were afterward filled with cement grout under a pressure of from 10 to 40 lb. per sq. in. In order to pour the concrete into the openings directly from the cableway, hoppers 6 ft. square were built around the top shaft of each tunnel, but only one shaft was used

for filling purposes, the second shaft, being of no practical value, was not used. The concrete was dumped directly from 2½-cu. yd. buckets into these hoppers and discharged down the shafts into the tunnels, where it was handled by men with shovels to within from 3 to 6 ft. of the roof, when work was stopped and the concrete allowed to set for at least a day. In the first few openings filled, it was thought best to build a concrete wall about 6 ft. thick of a medium dry concrete, to tamp it thoroughly, and to get a tight positive seal. As the wall did not prove to be water-tight, the method was discontinued. The method finally adopted for securing an absolutely tight seal was, as already partly described, to fill the tunnel throughout its whole length to within from 3 to 6 ft. of the roof, the men carefully spading and working this concrete with shovels so as to make a tight job. After this had set for 24 hours, it was carefully washed and cleaned and then a good flowing gravel concrete was dumped into the shaft, vent pipes having been properly placed, which vents also acted as tell-tales as the filling progressed. The back form was bolted up tight to the curve of the dam, and it was found that the dumping of this concrete down the main shaft would force concrete up and out of the back shaft to a height of 35 ft. or more above the top of the tunnel. The writers are of the opinion that, with a pressure of this kind and with a free-flowing concrete, every corner of the tunnel was bound to be tight, especially after the above described demonstration. As a further safeguard, however, a system of grout pipes was put in, and afterward grout was forced into these to fill any possible cracks.

In the ten small openings on the east side of the river, the same general scheme of filling was followed out, that is, a water-tight bulkhead was built 8 in. from the gate, leakage was carried off by pipes to the down-stream side of the dam, and concrete was poured to within 3 ft. of the top and allowed to set hard. Two 2-in. grout pipes were used, one on each side of the tunnel, and as close to the top as practicable, but below each keyway a T had been placed in the pipes and a nipple used so that its end would get within ½ in. of the top of the keyway. Very little grout was placed in these pipes; in fact, concrete in nearly all cases completely filled the tunnels.

One difficulty which should be guarded against in similar operations, was experienced in filling these tunnels: If the sand used was very coarse, as it was in one or two instances on this work, the concrete

would fail to run, and the tunnel would block itself. The remedy adopted by the writers in this emergency was immediately to dump 2-yd. batches of fairly rich mortar until the whole mass started moving again. As a rule, this remedy was satisfactory, and as soon as the mass started moving it came with a rush. In the worst case encountered, twenty-two 2-yd. batches of mortar were used to seal the top effectually. After grouting and setting a proper length of time, the openings were all tight, and showed very small negligible leaks which shortly clogged themselves.

Section D—General Organization of the Contractor and Power Company on the Work.

General Organization of Contractor's Forces.—The main features of the contractor's organization were as follows: A General Superintendent, with headquarters at the dam, was directly responsible to the New York office of MacArthur Brothers Company. He was also responsible for the execution of the contract, and worked directly with the Power Company's Resident Engineer on the job.

His assistants were: Superintendent of the Dam, Superintendent of Railroad, Superintendent of Quarries, Office Manager, and Master Mechanic. All other parts of the organization were handled under these general departments, each department being complete within itself, yet working closely with all the others.

The Superintendent of the Dam had charge of all day and night forces at work at the dam, except such as came under the Office Manager and Master Mechanic. He had a Night Superintendent, and, on both shifts, walking bosses and foremen in all the various departments of the work.

The Master Mechanic at the dam looked after the proper maintenance and operation of all machinery and plant, and all derrick runners, engineers, firemen, machinists, helpers, blacksmiths, etc., were under him. This department worked in very close relation with the Superintendent of the Dam, and derrick runners, cableway runners, pump men, etc., worked to a large extent under both departments. This relation between the Superintendent of the Dam and the Master Mechanic is not in general a wise one; in order to get the best results, the Master Mechanic should be a subordinate of the Superintendent of the Dam; however, in the case in hand, the scheme

worked satisfactorily. The machine shop was about ⅛ mile from the dam, and a large part of the Master Mechanic's time was spent there.

The Superintendent of the Railroad was in complete charge of all railroad operations outside of the Lock 12 and quarry yards. He had a force of trainmen, yardmen, trackmen, dispatchers, etc., under him, and was held responsible for the movement of all material over the railroad. His headquarters were at the junction of the main line and the quarry spur, 7 miles from the dam, known as Camp No. 4.

The Superintendent of the Quarry had charge of all quarrying and crushing operations at Zion and Ellison Quarries, and the camps at these two places. He had day and night forces, with walking bosses, foremen, a master mechanic, timekeeping and clerical force, commissary force, and all the skilled mechanics, engineers, etc., necessary for the work.

The Office Manager handled all commissary matters, purchases of supplies, timekeeping, bookkeeping and all financial matters. He had at Lock 12 a general office force of bookkeepers, timekeepers, stenographers, clerks, etc. All commissary managers at the various camps came under his jurisdiction, as well as timekeepers and material checkers there.

Commissary Department: Organization and Methods.—The Commissary Department deserves special mention, as it was a most important part of the work. Supplies for all four camps and for about 2 000 men were handled through this Department, all kitchens, cooks, as well as stores, coming directly or indirectly under it. The store at Lock 12 was not very well situated, and should have been larger. The writers believe that, had a little more thought been spent on its planning, it would have brought in better returns than it did. No elaborate stock was carried, and no particular attempt was made to realize profits from merchandising. The writers feel confident that it would pay the expenses of all commissary forces to run a store of this kind along proper lines. A store operated just outside of the limits carried a stock of merchandise and fancy groceries, and, even though big prices were charged, a good profit was made by the owner. The writers would recommend that, on a job of this size, the commissary store be a large airy building, centrally located, have regular counters, shelves, and tables for the display of goods; it should have a butcher shop as one department, and also a cold drink stand. It is to be

noted that the small cold drink side line operated in connection with the commissary practically paid the wages of two clerks alone in the summer, and one gave only about half his time to it. One general commissary inspector should be appointed, and he should be experienced in operating a store of this kind. All the various camp commissaries should be under him, and it should be his duty to inspect and watch constantly the character and class of goods demanded and to fill that demand.

It is astonishing how negro laborers and others on construction work will spend all they make for good clothes, candy, fancy groceries, etc., and a good profit can be made from these. It should be the aim to make these commissaries pay all expenses in connection with them and make up the deficit, if any, in the boarding houses, thus relieving the job of that burden as much as possible.

General.—In general, this organization worked out well, and there seemed to be very little friction; at the height of the work all departments seemed to be imbued with a spirit of co-operation and a desire to make high records on the concrete work.

Labor.—The labor problem proved very troublesome. Negro labor was used almost entirely, although other classes were tried. The negro, with all his unreliable features, proved the most satisfactory, but had to be treated properly to get the best results. A regular labor agent was employed to handle exclusively the Power Company's work. His headquarters were at the dam, and he reported to the Contractor's General Superintendent. He was a man who knew the Southern labor market well and was thoroughly familiar with all conditions. The greater part of the negro labor came from Florida, and it was necessary to keep a constant stream of men coming all the time. Some negro labor was brought from Mississippi, Memphis, Tenn., and Birmingham, Ala. All transportation was paid by the Company, and deducted later from the laborer's wages. If he remained and worked 60 days, he made his transportation, and it was returned to him.

Quite a few foreign laborers were brought, *via* Savannah, Ga., by sea, from New York City, being secured by New York agencies, but they were not satisfactory at the dam. They were then tried at the quarry and did so much better that for a long period the quarry labor camp was almost exclusively of foreigners. However, the loss was so great on the transportation of foreigners from New York that

labor of this class was finally abandoned, and negroes were put in at the quarries on both day and night shifts. The skilled mechanics, hoist runners, machinists, etc., all came from similar jobs scattered all over the South, and were of the type who follow big jobs of this kind around the country. Quite a few carpenters were brought from New York City, principally Swedes, and proved far more satisfactory than the local talent. The local white labor, skilled and unskilled, was absolutely unreliable, and of an exceedingly poor class. This source did not afford any help whatever in solving the labor question, and was effective in only one section of the work, namely, in floating and placing the coffer-dam cribs. This class was entirely ignored, there being only a very few regular employees drawn from it.

General Organization of the Power Company.—Supervising the Contractor's organization on the power-house foundations and dam, the Power Company's organization was in general as follows: Representing the Chief Engineer directly was the Resident Engineer. His responsibilities under the type of contract used were really those of a General Superintendent of Construction rather than those of an Engineer alone, as not only was he held responsible for the proper execution of the plans, proper inspection of all materials in the field, and the mixing and placing, but also for the working of the job by the Contractor in a proper manner, the disposition of his forces, his expenditures, the proper running and sanitation of his camp, the handling of commissaries, the placing and lay-out of the plant, etc. Furthermore, the Resident Engineer was clothed with full powers to back up and force attention to all orders and instructions given by him in the conduct of the work.

Under the Resident Engineer were two Assistant Engineers, a Chief Inspector at the quarry, and an Inspector of the railroad; one Assistant Engineer looking after the details of the office and all the night work in conjunction with the Resident Engineer, and all such general details of the job as the Resident Engineer turned over to him for attention. The other Assistant Engineer, with his assistants, not only looked after the proper handling and placing of the concrete, but at all times kept close track of the Contractor's working organization on the dam to see that it was handling the work efficiently. He conferred constantly and worked almost entirely with the Contractor's Superintendent on the dam, his main duties being to look after the construction

on the dam and power-house only, to see that all features were according to the specifications, and that the forces were properly organized and handled.

A day and night inspection was maintained at the quarry, the Chief Inspector handling the day shift and the inspection work on that shift. He was assisted by a timechecker, clerk, and night inspector. He was held responsible for the proper inspection of all crushed and cyclopean stone, and saw that only clean materials were loaded. He watched the loading at the quarry, saw that all stone was washed before going to the crushers or to the dam as cyclopean, and measured all cars of crushed stone before they were pulled out. He also was held responsible for the proper checking of all materials and labor used by the contractor there, and reported any inefficient handling of men or equipment. The Night Inspector performed the same duties at night, reporting to the Chief Inspector. The Power Company's forces were provided with a comfortable house and office entirely separate from the Contractor's forces. They, however, took their meals at the Contractor's mess hall.

The Inspector of the Railroad performed the same general duties on the railroad as other inspectors, and his assistant also checked time and materials, as already outlined. His duties, however, were not as important as those of the other inspectors.

A force of time and material checkers, entirely independent of that of the Contractor, was maintained in each camp, and vouchers and pay-rolls were approved only on the Power Company's check. All expenditures for material and labor had to receive the approval, in writing, of the Resident Engineer, and this approval was essential to the passage of any voucher for payment.

General day and night forces of inspectors, checkers, timekeepers, etc., were maintained by the Power Company at the dam. All the day inspection work was performed under a Chief Inspector, and he, with his inspectors at the dam and at the mixer, checked all forms, looked after the proper mixing, placing, and working of concrete, the proper preparation of the surface of old concrete, saw that all bolts and reinforcing were properly set, etc. The inspectors on the dam and power-house gave orders to the concrete foremen and walking bosses where they concerned the proper working of the concrete and the cleaning of the surface of old concrete before placing new concrete

on it. They had the authority to prevent any of the Contractor's men from commencing to place concrete if the forms were improperly cleaned out. Great stress was laid at all times on the proper cleaning of the concrete. The mixer inspectors watched the proper proportioning of the mix and the quantity of water necessary, receiving their instructions from the inspectors on the dam. At the mixing plant, there was also a cement checker on each shift.

The night shift organization was handled in the same manner, with an Assistant Engineer in general charge for the Power Company, and a Chief Night Inspector under him. All the survey and lay-out work was handled by two small parties of two or three men each. One of these parties was assigned to the dam and another to the power-house. All levels, lines, grades, etc., were given by these parties. Before and after forms were set up by the carpenters, the lines and levels were given by one of these field parties, and the inspectors would allow no concreting in a form until it was "O. K'd." as to grade and line by the Chief of the Party.

This system of handling the inspection and survey work proved most satisfactory, and is recommended for similar work.

Power-House Superstructure and Equipment.

As previously mentioned, the construction of the power-house superstructure and the installation of machinery was done by the Company's own forces. In October, 1913, the organization of the Company's construction forces was begun, most of the men being taken from Gadsden, where, as noted early in the paper, a 10 000-kw., steam turbo-generating station had been constructed.

A camp was constructed near the main camp of the Contractor's forces, and independent mess halls were provided. Storage yards for structural steel, brick, machinery, etc., were constructed part way down the Low-Level Line, and a traveling gantry crane, later erected in permanent position on the up-stream side of the power-house, was placed in these yards for the purpose of unloading and storing heavy machinery parts.

Steelwork.—On November 4th, the foundations were in such shape in the power-house that steel erection was started. A spur track was built from the Low-Level Line in the bottom, entering the west bay of the power-house on a trestle at Elevation 370, approximately, it being

planned to bring all steelwork, machinery, etc., in on flat cars here and remove it with first a locomotive crane and later with the permanent 100-ton crane. A 30-ton locomotive crane was set up inside the power-house for the purpose of erecting all columns and cross-girders. This crane had a 50-ft. boom with a 30-ft. extension. On Figs. 45 and 46 this crane is shown at work erecting columns, and also the track on which all steel and other materials were brought in. As soon as the steel was in condition to receive the 100-ton crane, it was erected, and the locomotive crane was withdrawn for the purpose of loading cars in the yards. A traveling stiff-leg derrick was then erected on the heavy cross-girders above the 100-ton crane, and it handled the remainder of the steel erection, the 100-ton crane taking the steel from the cars below and delivering it to points under the traveling derrick.

Brickwork.—After riveting was sufficiently advanced, the brickwork was started on a previously moulded concrete water-table. All the window sills, cornices, and ornamental work were of concrete blocks, moulded and cast on the work. All concrete block forms were of cast iron, and the results obtained were very good. Gravel and coarse sand were used for making the concrete. They were mixed fairly dry, being well packed and rammed into the moulds.

Erection of Units.—The foundation rings and shell of the units came in sections. These sections were loaded by the 30-ton locomotive crane on flats and delivered to the 100-ton crane in the power-house. These sections were then assembled on the floor adjoining the foundation on which they were to be set, and put in place, properly lined and leveled up, grouted, and then concreted. The type of speed ring and casing used permitted it to be set directly on the foundation previously prepared. It was blocked into permanent position by jacks and holding-down, foundation blocks, and then solidly concreted. The first speed ring was set for No. 4 Unit on January 8th, 1914, and this unit went into commercial service on April 12th, 1914, the others following rapidly thereafter. The first unit was operated through a temporary switch-board and transformer-house set up outside the main building, in order to start selling this power at the earliest possible moment. This allowed the setting up complete of the main busses, switch-boards, and wiring, without current being on them. Later, when these three units were all installed and everything in readiness, the unit that

had been operating temporarily was pulled out of service, the transformers put in their permanent locations, and the few connections between the unit and switch-board easily and quickly made.

Gates.—Penstock gates were set at the time the units were being prepared for service. Some trouble was experienced on all gate frames on account of the castings being too light and warping or springing. This was true of the spillway gates and the guides for the screens in front of the penstock gates. It is almost impossible to block these to exact line, and, in the cases in question, the clearances were entirely too small. Also, the method of setting gate frames in the original pour of concrete around them should be avoided. In view of the experience gained on this work the writers recommend strongly that in similar designs the following points be observed in the design and erection of cast or structural gate frames:

1. See that ample clearances are allowed, giving wide bearing faces to make up the excess width allowed.
2. All faces should be machined true and square, and should be carefully inspected with that end in view at the mill or factory.
3. Grooves and pockets with proper anchorages should be left in the concrete, the frames should be set up after the mass of concrete is poured, and then carefully lined, anchored, and grouted in place.

A gantry crane which traveled on the front side of the power-house, at Elevation 425, handled and set all the large penstock gates. These gates weighed about 12 tons each, and were operated by large cylinders, using oil under pressure. The spillway gates were all assembled and riveted in the assembly yard, some distance from the dam. They were then loaded on cars and delivered to a scow, built for the purpose, just above the dam. They were towed to the front of the openings, and put in place. These gates were operated by a traveling car which, through a flexible coupling, engaged a gear operating the hoisting mechanism of each gate. This traveling car was in duplicate, one electrically operated, the other steam-driven.

Reservoir Clearing.

Of the 4 700 acres of reservoir land, 1 700 acres were more or less heavily wooded. A thorough investigation showed that there would

be no actual ill effects to the health of the community at large, by leaving this timber standing, but the temperament of the hill people residing in the neighboring territory, and their respect for the law, in so far as it may assist them in obtaining compensation for imagined damages, made it appear prudent to clear the reservoir. This decision was strengthened by the fact that a power company in Georgia, which had not cleared its reservoir, was having endless legal trouble from damage suits filed against it. After consultation with the health officials of the State, it was decided that no timber should be left standing, or in a fallen position, between the 420-ft. contour, the normal lake level, and the 410-ft. contour, the limit of the draw-down. Wherever merchantable timber was within a reasonable distance of the railroads, it was sold, and a quantity of pine timber was converted into charcoal; whatever could not be disposed of in either way was burned on the ground, if possible.

Transmission Lines.

The standard line construction adopted by the Company involved the transmission of current at 110 000 volts and distribution at 22 000 volts. For the former, the double-circuit, galvanized-steel towers were adopted. These towers carry two ground wires of $\frac{3}{8}$-in. Siemens Martin, and six No. 00 copper, 7-strand conductors, drawn to 55 000 lb. per sq. in. in tensile strength. The towers were of three types: Type A used in rough country, weighs 4 600 lb., is 68 ft. high, and has a 10-ft. spacing of conductors vertically and 15-ft. horizontally on the top and lowest arms, and 16 ft. 6-in. on the intermediate arm. The base of this tower is 15 ft. square. Type B towers were used as strain towers; they weigh 4 700 lb. and are of the same general design as the other types except that they have bases 17 ft. square; these towers are used at angles between 3° and 35° and at every $2\frac{1}{2}$ miles on the lines. The Type C tower is used in flat country in connection with Type B towers, the latter being placed at each mile point. These towers weigh 3 600 lb., are 65 ft. high, and have bases 16 ft. square. The ground clearance allowed was 25 ft., and the towers were located so that with a $\frac{1}{4}$-in. coating of ice and 8 lb. wind pressure, this clearance would be maintained. The normal spacing for Type A towers is 700 ft., and for Type C, 600 ft.; the maximum allowed spacing for Type A is 1 200 ft., and for Type C, 900 ft.

The insulators used on the 110 000-volt lines were of three makes: the Ohio Brass, Thomas, and Locke. The strings were made up of 6 units on suspension and 7 on strain. The disks are 10 and 12 in. in diameter. The 6-disk strings were tested to 350 000 volts dry and to 255 000 volts wet, before flash over. The test for mechanical strength consisted of a pull of 5 000 lb. applied in the direction of the axis.

The right of way secured for transmission lines was 100 ft. wide. The towers were set on the middle of this strip, and, 10 ft. from the edge, there was carried an all-copper telephone circuit of No. 8 hard-drawn wire, on 22-ft. creosoted poles, 175 ft. apart. On the telephone lines, porcelain insulators, designed for 6 600 volts, were used on a single cross-arm. The line is transposed every fifth pole.

Wagons were especially designed for the transmission line surveys, and their equipment was very compact. Each wagon contained sleeping accommodations, and cooking and table utensils for a party of thirteen men. A negro cook and a negro who acted as driver and general utility man were carried with the party.

The sequence of construction was as follows: When the right of way was secured, a clearing gang, normally consisting of sixty men and two foremen, cleared the line. Immediately following the clearing gang was the telephone gang, consisting of a foreman and twelve men. This gang erected poles and strung the line complete, tying into the public long distance telephone lines at convenient points, so that at all times there was easy communication with the main office. Following a short distance behind the telephone gang was the foundation gang of seventy-five men and three foremen. This gang dug holes, set the stubs of the towers, and back-filled, or set the rock-anchors, as the case might be. The assembling and erecting gangs of forty men total and two foremen for the two gangs, followed as closely as convenient. The stringing gang, of sixty men and three foremen, hung insulators, and strung the ground wires and conductors, finishing the line ready for service.

Fig. 50 shows part of the stringing gang at work on the line from Lock 12 to Anniston, the right of way being occupied by the tower line and a pole line carrying 22 000 volts. Fig. 51 shows the Sylacauga-Alexander City, 22 000-volt line. In this line, the conductors were carried on wishbone-type cross-arms, and the ground wire on

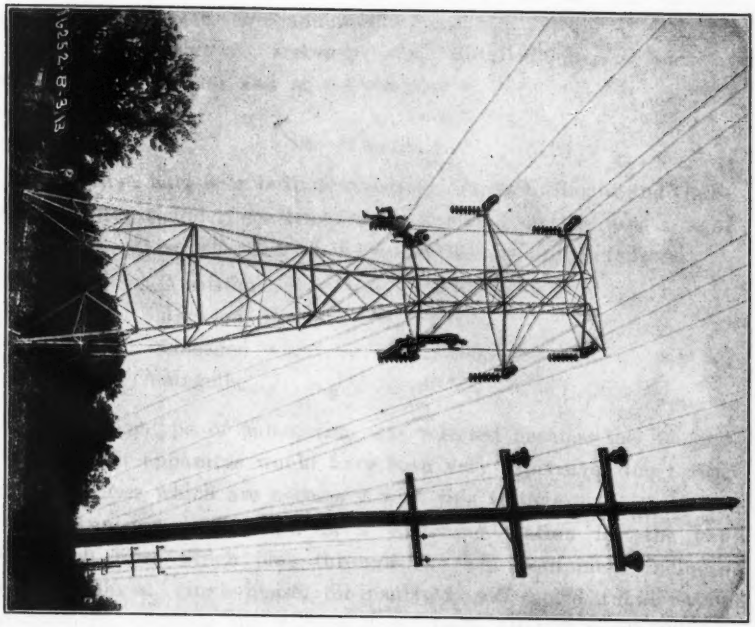

FIG. 50.—STRINGING COPPER CONDUCTORS ON TRANSMISSION LINE OF 110 000 VOLTS.

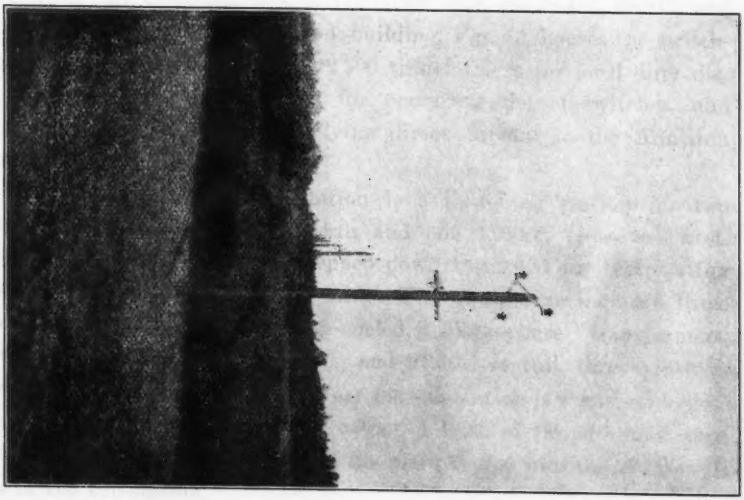

FIG. 51.—DISTRIBUTION LINE FOR 2 000 VOLTS, USING WISHBONE TYPE OF CROSS-ARM.

a bayonet. On all 22 000-volt lines, the telephone line was carried on the same pole with the conductors.

Electrolytic lightning arresters were installed on all lines at the generating stations and at sub-stations.

Sub-Stations.

Sub-stations have been built at Anniston, Jackson Shoals, and Gadsden, and one is under construction at Magella, on the outskirts of Birmingham. The capacities of these sub-stations are as follows:

Anniston	6 000 kv-a.
Jackson Shoals	6 000 "
Gadsden	12 500 "
Magella	40 500 "

The outdoor-type of sub-station was selected because the housing of 110 000-volt apparatus would have been very expensive, due to the large clearances which are necessary with this voltage.

The Anniston Sub-station is a switching station for the two 110 000-volt lines which pass through it. The equipment includes three 2 000-kv-a., single-phase, oil-insulated, self-cooled tubular-type transformers, stepping the voltage down from 110 000 to 22 000 for distribution in the Anniston district. The efficiencies of these transformers at full, three-quarters, and one-half load, are 98.4%, 98.2%, and 97.7%, respectively. A small brick building, Fig. 53, houses the switchboard, three 667-kv-a., 22 000 to 2 300 transformers for local duty distribution, the storage batteries for operating the oil-switches, and a motor generator set for supplying direct current to the Anniston Street Railway.

The Jackson Shoals Sub-station is a switching station for two 110-kv. from the north and south and one 110-kv. from the west. At this point, the voltage is stepped down to 22 000 for distributing lines to the north, south, and west. The equipment includes three 2 000-kv-a., oil-insulated, water-cooled, single-phase transformers, with efficiencies of 98.05%, 97.9%, and 97.5%, at full, three-quarters, and one-half load, respectively. Near the sub-station is the small hydro-electric plant generating at 2 300 volts. A bank of transformers steps this voltage up to 22 000 volts, and the plant is tied into the 22 000-volt bus of the sub-station.

The Gadsden Sub-station is a distributing as well as a step-up station. The generating voltage of the steam plant is stepped up from 2 300 volts to 110 000 or 22 000 volts, or the 110 000 voltage of the transmission lines is stepped down to 22 000, as the case may be. The equipment of the station includes two banks of three transformers each, and a spare-all single-phase, oil-insulated, and water-cooled—each of 2 100-kv-a. capacity. These transformers have three windings, for 2 300, 22 000, and 110 000 volts. The guaranteed efficiencies at full, three-quarters, and one-half load are 98.3%, 98.1%, and 97.6%, respectively.

The Magella Sub-station is a distributing station for three 110 000-volt lines, two from the south and one from the east. The station will step down from the 110 000 volts of the transmission lines to 22 000 volts and to 13 200 volts for distribution, the latter being for distribution into Birmingham. Provision has been made for increasing the capacity of this station from 40 000 to 67 000 kv-a. The equipment includes three banks of three transformers each, and a spare-all single-phase, 4 500-kv-a. capacity, oil-insulated, and water-cooled.

Fig. 52 shows the bus structure of the sub-station at Anniston, which is typical of the others. It is built of towers and girders, this construction having been found to be more economical than an arrangement of towers alone. All the material in the structure is galvanized steel. The weights of the structures are: Anniston, 22 tons; Jackson Shoals, 35 tons; Gadsden, 30 tons; and Magella, 50 tons.

The 110 000-volt busses are No. 00, B. & S. gauge, copper wires, supported horizontally by seven, and vertically by six, 10-in. disk insulators. The busses are 8 ft. apart and are 5 ft. from the nearest steel.

The oil-switches are of the out-door, solenoid-operated, remote-control type, operated from storage batteries in the switch-houses.

Provisions are made at each sub-station for the repair of transformers. There are electrolytic lightning arresters on all 110 000- and 22 000-volt lines, as a protection against the severe electric storms of the region.

It is proposed to standardize future installations of sub-stations into capacities of 3 000, 6 000, and 10 000 kv-a. The bus structure, being made up in unit panels, will be adapted readily to this standardization.

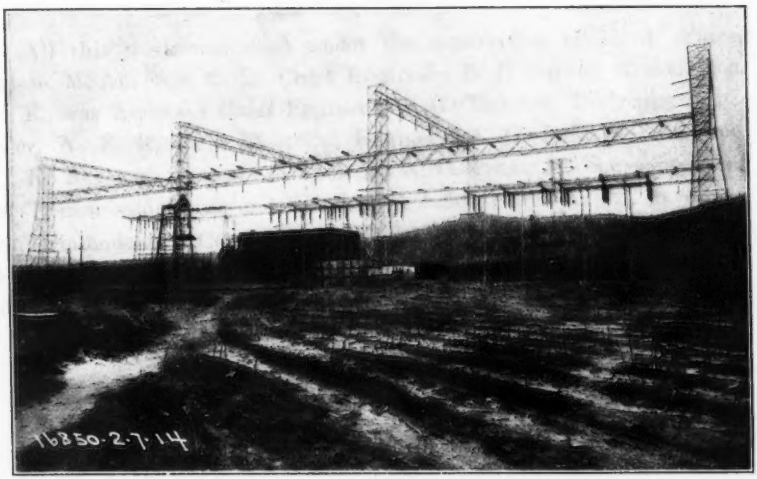

FIG. 52.—OUTDOOR SUB-STATION AT ANNISTON, ALA.; CONSTRUCTION IS TYPICAL OF ALL SUB-STATIONS.

THE GAUGE OF RAILWAYS, WITH PARTICULAR REFERENCE TO THOSE OF SOUTHERN SOUTH AMERICA.

Discussion.*

By Messrs. T. A. Corry, Frank Foster, H. Deane, and G. F. F. Osborne.

T. A. Corry, M. Am. Soc. C. E. (by letter).—Mr. Lavis' figures show that more than 60% of the Argentine Railways are broad-gauge, and only about 8% are standard. This fact, taken in connection with the lack of ballast and consequent difficulty in keeping the track in good surface, proves unquestionably that if only one gauge is to be adopted, the broad-gauge is the proper one for the Argentine, for Mr. Lavis is quite right in his remarks on the relative stability of broad- and narrow-gauges. Mr. Corry.

For such mountainous countries as Bolivia, Peru, Ecuador, Colombia, and Venezuela, the advantages of the standard gauge over the meter-gauge may be questioned for three reasons:

First. With the meter-gauge the capacity of 95% of the railways required, for the last 30 years and the next 30 years, to handle the available traffic would be quite ample.

Second. Sharper curves can be used on narrow-gauge than on wide-gauge for the simple reason that the rigid wheel base is shorter on both cars and locomotives for the narrower gauge, and the possibility of using sharper curves very greatly reduces the graduation item—a heavy one in traversing the slopes of the Andes, on either the west or east side, in the countries mentioned.

* Continued from April, 1914, *Proceedings*.

Mr. Corry.

Third. It is good business to use a small gun and small shot for small game, especially when expenses are reduced thereby.

It is axiomatic, of course, that a considerable amount of traffic, even in a mountainous country, can be handled at less cost per ton per mile on a standard gauge than on either of the narrower gauges, and the standard is the more economical even if it does cost more to construct.

As to speed, on curves of 100-m. radius (328 ft.), the safe limit is about 28 miles per hour, with the practical elevation slope of 6°, and this speed can be made without difficulty on either 3-ft. or meter-gauge. To refer to a concrete example, take the section of the Peruvian Southern Railway from Mollendo, on the Pacific, to Puno, on Lake Titicaca (Plate XXIX). This road is of standard-gauge, 326 miles in length, and was built in 1868-73, at a cost of 42 000 000 soles (at that time the sol was worth 48 pence, or, say, 97 cents). The maximum gradient was 4%, and the minimum radius of curve 100 m. (328 ft.), and the minimum was used very frequently.

The Mollendo Division is 172 km., or 107 miles, in length, and cost 12 000 000 soles. Besides numerous short tangents, it has six of from 2 to 7 miles in length, aggregating 25 miles. On the remaining 82 miles there are 421 curves, an average of 5 curves per mile. More than half these curves are of only 100-m. radius with an angle per mile of more than 250 degrees.

The Puno Division is 352 km. (219 miles) in length, and cost 30 000 000 soles. It has twelve tangents varying in length from 2 to 12 miles, comprising 46 miles, exclusive of those of less than 2 miles in length. The curve section is 173 miles in length and has 783 curves, an average of 4½ curves per mile, the larger number of which are on rough ground, and principally solid rock.

The total daily average tonnage, both ways, has never exceeded 600 in any of the 41 years of the road's existence. The average haul is large, being some 200 miles.

Whether it might have been advisable to have built this road with a 3-ft. gauge, using curves of only 80 m., is debatable on the ground of smaller first cost.

To give another illustration: A few years ago the writer was instructed to make a survey from a point on this road to a river of the Amazon Valley, less than 300 miles in length. The bases given were: maximum gradient, 3%; minimum radius of curve, 120 m.; and gauge, 3 ft. On these bases, the estimated cost reached the sum of $12 500 000, which was a prohibitive one for the traffic and advantages expected.

A resurvey of the roughest part (60 miles), using a gauge of 30 in. instead of 3 ft., with a minimum radius of curves of 50 m.

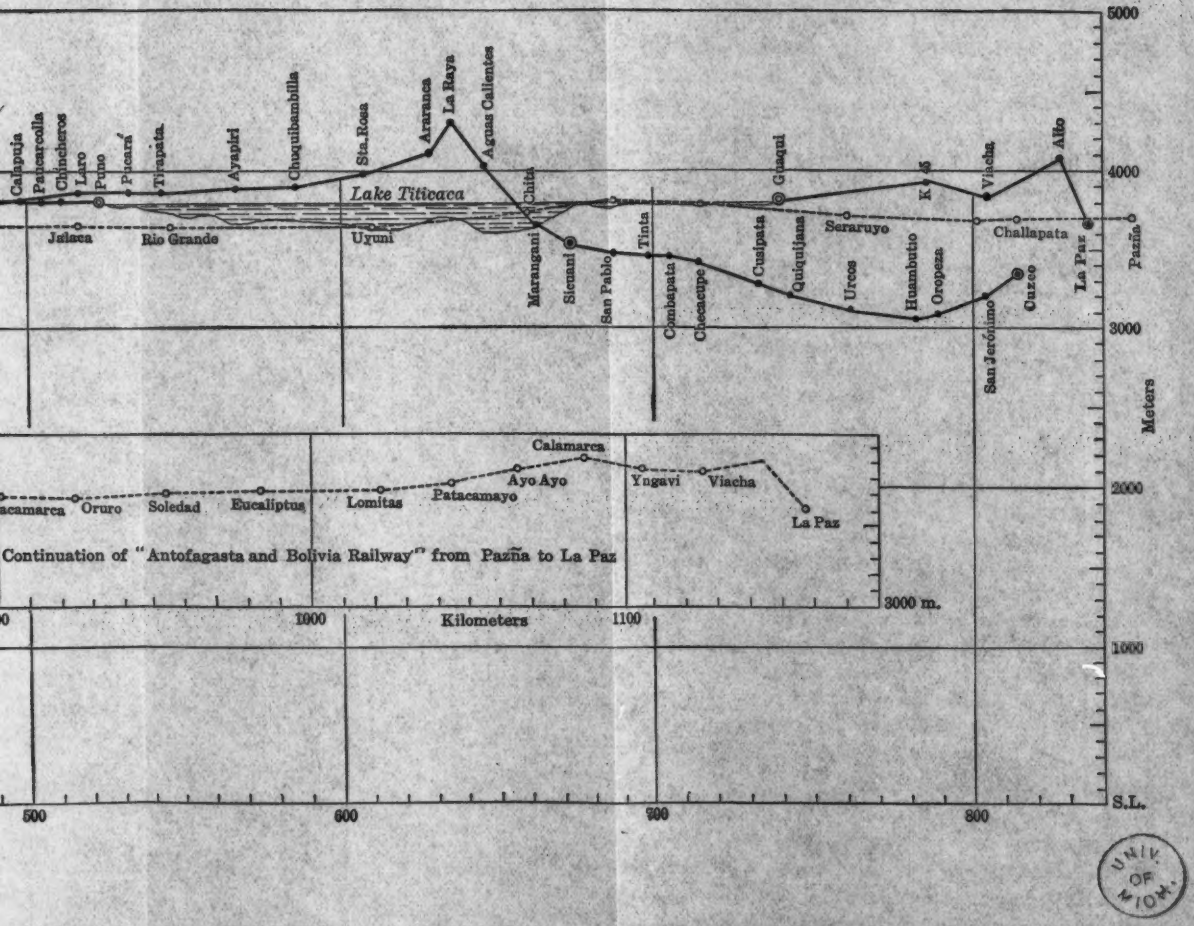
PLATE XXIX.
PAPERS, AM. SOC. C. E.
SEPTEMBER, 1914.
CORRY ON
THE GAUGE OF RAILWAYS.



UNIV. OF ILL.

and a gradient of 5% (for use with Shay locomotives), resulted in a reduction of $3 500 000, or nearly 30 per cent. The principal reduction was due to the sharper curves, by which much heavy work and all the tunnels were avoided. The expected traffic would hardly reach 300 tons per day for the next 20 years. Mr. Corry.

The Antofagasta and Bolivia Railway Company is changing its 30-in. gauge to 1 m., so that now there are in Bolivia somewhat more than 800 miles of railways—all of 1-m. gauge.

In 1912, the total tonnage, including company material, handled was 1 600 710, or nearly 4 400 per day, the average distance hauled being about 130 miles. In view of the great expense being incurred by this road in changing its gauge to 1-m., it is to be presumed that the relative merits of 1-m. and standard-gauge have been carefully considered.

While the writer is not an advocate of narrow-gauge railways, it must be admitted that there are still some mountainous districts, where their use, especially as feeders, is advisable, even if it should prove necessary after a number of years to widen the gauge, and possibly at the same time make other improvements in the matter of alignment, gradients, etc. To put it another way, it may often be inadvisable to build now, for traffic to be handled, say, 40 years hence.

Frank Foster, M. Am. Soc. C. E. (by letter).—In his able paper on railway gauges in South America, Mr. Lavis puts too lightly to one side what appears to the writer to be the principal advantage of the narrower gauges. Mr. Foster.

The Argentine broad-gauge (5 ft. 6-in.) will not allow of shunting with main-line engines on curves of 200 ft. radius, and requires turn-outs with curves of 600 ft. radius for goods trains; and curves well maintained of less than 1 600 ft. radius are rough for main-line running.

In comparison, the meter-gauge stock can circulate on curves of 120 ft. radius, can use turn-outs with curves of 250 ft. radius for goods service, and curves well maintained of 1 000 ft. radius can be taken comfortably at full speed on the main line.

The writer does not wish to imply that broad-gauge stock could not be constructed to circulate under these conditions, for they certainly could, but always at the sacrifice of velocity.

Mr. Lavis quite correctly points out that the broad and standard gauges have enormous advantages in speed over the narrow gauges, but, in fairness, this principal advantage of the narrow-gauge, namely, normal velocity on curves of smaller radius, should be equally extolled. As this is, in the writer's opinion, the unique advantage of the narrow gauges, their use in the Argentine is only justified in mountainous districts, and is to be deplored in the plains, for, without any financial or physical advantages, they have bred costly transhipment

Mr. Foster.

which can only be avoided by a duplication of expenditure, frequently unjustifiable.

Unfortunately, the original railways in the Argentine were constructed of the 5 ft. 6-in. gauge in preference to the standard 4 ft. 8½-in.; and although any idea of correcting this error now or in the future would be financially unsound, as the advantages could in no way compensate the outlay, yet the writer is of the opinion that Mr. Lavis in no way exaggerates the advantages of the standard-gauge as compared with those of the broad-gauge.

An examination of the minimum construction and maximum rolling-stock gauges of the broad-gauge of the Argentine (Fig. 3) shows them to be very similar in dimensions to those of the standard-gauge in the United States, which indicates that in the Argentine no use is made of the wider gauge.

On several occasions the advisability of enlarging the rolling-stock gauge has been under discussion between the officials of the railways and the Argentine Government Railway Board, but it has been resolved, for the reasons given by Mr. Lavis, that there was not sufficient advantage, either in locomotives, coach, or wagon stock, even though the cost of increasing the construction gauge was not prohibitive. For

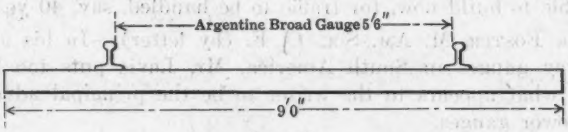


FIG. 13.

instance, the broad-gauge lines of the Argentine at that time had no tunnels, and there are very few over-bridges.

The carrying capacities of the Argentine broad-gauge and the United States standard-gauge are in reality the same, the only appreciable difference between them being the position of the rails, that is, the gauge.

The rail position of the Argentine 5 ft. 6-in. gauge, on 9-ft. sleepers, Fig. 13, represents a very distinct disadvantage to maintenance, as the length of the sleepers outside the rails is not sufficient for adequate support; theoretically, the maximum pressure transmitted by these sleepers is at their extremities instead of under the rails, as is the case with standard-gauge and 9-ft. sleepers, and is at that point 35% in excess of the average pressure instead of 10 per cent. These disadvantages exist, to the writer's practical knowledge, and, in earth ballast, cause excessive pumping at the extremities after rains, and frequent breakage of the sleepers at the center.

In this respect the Argentine meter-gauge tracks, with 6-ft., and in some cases 6 ft. 8-in., sleepers, have better proportions, but the overhang of the rolling stock, shown by Fig. 3, is out of proportion—for

Mr. Foster.

good maintenance on earth ballast—both to the gauge and to the sleeper length. This practically results in greater expenditure in maintenance, rougher riding, and reduced velocity, as compared with the broad gauge. Owing to the general absence of stone in the plains, the majority of the railways in the Argentine are earth-ballasted, except where the traffic is dense or in the few districts where stone exists.

The ratios between the rolling-stock gauge, length of sleepers, and gauge of track are given in Table 30.

The sleepers used in the Argentine are of a specially hard native timber (*Quebracho colorado*), of a density of 80 lb. per cu. ft., which permits the use of a dog-spike connection. These sleepers have a life equal to that of the rails they carry, in many cases exceeding 35 years.

Dense forests of these trees grow in the Northern Provinces of the country, and the soundest timber for sleepers is obtained from the branches sawn in two. The sawn side is laid downward for the bearing on the ballast and the upper side is adzed, as they are rough in section and all the sap-wood rots away entirely within a couple of years. A typical section of one of these sleepers, after the loss of the sapwood, is shown in Fig. 14.

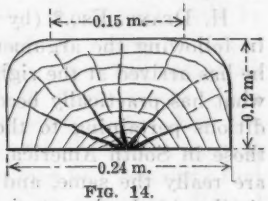

FIG. 14.

Sleepers can be obtained square sawn from the main tree trunk, but are not to be preferred as they frequently split on exposure or spiking. Consequently, up to certain lengths, the cost per cubic foot is more or less constant, but for a length of more than 9 ft. the cost increases considerably.

As there are no native timbers other than the quebracho and similar hardwoods available in the Argentine, apart from the fact that legislation actually calls for the use of the timber of the country, everything is in favor of the use of quebracho in preference to any other timber on these railways.

TABLE 30.—RATIOS BETWEEN THE ROLLING STOCK, GAUGE, LENGTH OF SLEEPERS, AND GAUGE OF TRACK.

	Track gauge.	Sleeper length.	Rolling stock width.	Ratio of sleeper length to track gauge.	Ratio of rolling stock width to track gauge.	Ratio of rolling stock width to sleeper length.
Argentine: Broad-gauge.....	5 ft. 6 in.	9 ft. 0 in.	11 ft. 2 in.	1.63	2.03	1.24
Argentine: Narrow-gauge.....	3 ft. 3⅜ in.	6 ft. 0 in.	10 ft. 6 in.	1.83	3.20	1.75
United States: Standard-gauge..	4 ft. 8½ in.	8 ft. 6 in.	10 ft. 3 in.	1.80	2.18	1.21
United Kingdom: Standard-gauge	4 ft. 8½ in.	9 ft. 0 in.	9 ft. 0 in.	1.91	1.91	1.00

Mr. Foster. Therefore, the Argentine broad-gauge lines will probably continue to use sleepers of this length despite the serious disadvantage to maintenance indicated by the ratios given in Table 30.

On the level plains of the Argentine, curvature has not caused serious inconvenience thus far, but the waste of space in valuable terminals by the length of one-in-eight turn-outs (85 ft.) is an additional serious defect in the broader gauge, whereas, in the writer's opinion, there are no advantages of any kind in the use of the 5 ft. 6-in. gauge in the Argentine, as compared with those of the 4 ft. 8½-in. gauge.

The writer has not entered into the question of methods of transportation, but would point out that on the Buenos Aires Western Railway it is usual to run trains of more than 2 000 tons gross weight with locomotives weighing more than 100 tons. These trains at times attain a length of 2 500 ft. On that railway, wagons with carrying capacities of from 40 to 45 tons represent more than 80% of the total carrying capacity of those in service.

Mr. Deane. H. DEANE, ESQ.* (by letter).—The writer has been much interested in following the arguments set forth by the author, and believes that he has arrived at the right conclusion when recommending for adoption what has practically become the standard and world gauge. The conditions pertaining to the problem in Australia differ somewhat from those in South America, in that the interests of the Australian States are really the same, and there is a tendency toward one or at least a similar kind of control in all matters. In the case of the railways there have taken place, for many years past, annual meetings of the officers and Commissioners who have charge in each State, and the desire always has been to work for one common object, the good of all. In South America there are many independent States, the Governments of which are not actuated by any desire for the common good; at the same time, it must be felt that individual interests would best be served if there were one gauge common to the whole country, for when the railways meet on the borders, interchange would thereby be facilitated.

In spite of what has been said in a few quarters as to the inadequacy of the 4 ft. 8½-in. gauge to meet all conditions of crowded traffic, it must be recognized that a medium gauge suitable for the vastly preponderating ordinary conditions should be adopted—one that is not so wide as to be prohibitive in cost when used in a country where the population is sparse and traffic is light. The 4 ft. 8½-in. gauge has been proved to meet all requirements fairly, and it is doubtful whether much more could be done with any much wider gauge than is achieved in the United States on the 4 ft. 8½-in.,

* Recently Engineer-in-Chief for Commonwealth Railways, Melbourne, Australia.

seeing that to get the full theoretical advantage of very much wider gauges, rolling stock would have to be built of very unwieldy dimensions, and this very unwieldiness would tend to reduce its economic value. Mr. Deane.

The case of India seems to show that a gauge much wider than 4 ft. 8½-in. would sooner or later prove a mistake. Railway construction was commenced in that country on a 5 ft. 6-in. gauge, but after a time that gauge seems to have been found to be inconveniently wide, and recourse was had to the meter-gauge for large extensions. The mileage of the railways on this gauge seems to be about 40% of the whole system. Had the 4 ft. 8½-in. gauge been adopted at the outset, there would probably have been no meter lines. Mr. Lavis has shown that, where the meter-gauge was thought necessary, the 4 ft. 8½-in. gauge meets the conditions quite as well. The writer proved that himself when constructing the Wolgan Valley Railway in New South Wales, and this has been mentioned by the author.

In selecting a gauge as a standard in any country, it should of course be borne in mind, that sooner or later connections will be made with outside countries, when all the evils of breaks of gauge will be experienced if the matter has not been previously adjusted.

There is one argument in favor of the 4 ft. 8½-in. gauge which should not be lost sight of. The present tendency is to adopt the same standards for mechanical details throughout the world, so that when an article is ordered from a distance there may be a certainty that it will fit into its place. The chief manufacturing countries—United States, Canada, Great Britain, and those of the continent of Europe—are engaged in building locomotives and other rolling stock to the 4 ft. 8½-in. gauge, and it is clear that if, in a certain country, there is a sudden demand for rolling stock which cannot be met out of its own resources, orders placed in any of the countries mentioned could be much more promptly met if the country ordering uses the same gauge; whereas, with a different gauge, there would necessarily be special designs, special patterns would have to be made, and so on.

G. F. F. Osborne, Assoc. M. Am. Soc. C. E. (by letter).—The writer has been connected with the administration of a railway comprising a section of 5 ft. 6-in. gauge adjacent to a large port, and a meter-gauge section, farther away, built as an extension of and as a feeder to the 5 ft. 6-in. section. Although the accounts and statistics of the two gauges were kept separately, both were worked as one system by one establishment of administrative and executive officers, and members of the staff in all grades were transferred, as occasion arose, without reference to the section on which they were serving or to serve. The results, therefore, afford a very fair basis for judging the relative operating merits of broad- and narrow-gauge for the conditions there obtaining. Mr. Osborne.

Mr. Osborne.

Both lines are built over flat country intersected with waterways. There was very little cutting (practically none) on either system. The area served by the broad-gauge is densely populated; that served by the narrow-gauge more sparsely so. In both cases the individual inhabitant has a very small traffic value, either by his personal journeys or as a producer or consumer.

Before these lines were built, the country was served by a well-organized system of water carriage, which still exists; and competition is severe. The system has arrived at its present state partly by direct construction, but partly by the absorption, by purchase, of other lines; and their purchase price is now shown in the capital accounts as a lump sum. The broad-gauge section bears the brunt of the expenses due to terminals, has a heavy suburban traffic, and is generally constructed on a higher standard than the meter-gauge. On the other hand, the possible extension of the broad-gauge to replace the meter-gauge (now in progress over some 60 or 70 miles) has led to the construction of bridges having spans of 60 ft. and greater on the broad-gauge standard, and the expense (a considerable item) is charged to the meter-gauge. Another broad-gauge railway reaches the port by running powers over the quadruple portion of the broad-gauge section and two of the four tracks are necessitated by this traffic (which has not been here considered). The meter-gauge stops about 125 miles from the port, and all through traffic is transhipped at the point where the gauge changes.

The system is a network rather than a line, and has many branches. The longest distance run by a through train is 150 miles on the broad-gauge and 335 miles on the meter-gauge. Over the whole system the average haul of a passenger is 23 miles; of freight, 192 miles. Practically the whole staff is housed in buildings belonging to the administration and charged to the capital of the undertaking. Station buildings, houses, platforms, and similar structures are of masonry. The system is soundly built, well equipped, and adequately maintained.

Practically all the passenger stock is fitted with automatic brakes, but this is true of only a small percentage of the freight stock. The busier parts of both sections are worked on the block system, with token instruments; the remainder is worked on the written "line clear, authority to proceed" system. Signaling is normal danger.

The statistics in the tables are for 1912, and are derived from the half-yearly analysis of working the system; the sum or mean of the figures for the two half-years being taken. The error (if any) thus caused is not sufficient to affect the comparative value of the figures.

Before considering the operation statistics, it may be stated that the meter-gauge is being extended through country where the line is not expected to pay in itself for some time after opening, and profits have to be looked for in the increase in traffic brought thereby to exist-

ing portions of the system. The character of the traffic carried is shown by Table 32. Mr. Osborne.

TABLE 31.

Physical Characteristics.	5 ft. 6-in. section.	3 ft. 3½-in. section.
Mileage	512	1 117
Of which is Single-track	397	1 117
Double-track	94	
Quadruple-track	21	
Ruling gradient	1:300	1:200
Sharpest curve: Radius, in feet	1 000	500
Actual capital, cost per mile of line	$90 000	$35 500
Of which approximately is due to:		
Preliminary expenses and general charges	2 250	2 350
Rolling stock	21 750	6 725
Track, works and structures	66 000	26 425
Maximum weight of rail	90 lb.	50 lb.
Width of formation	20 ft.	16 ft.
Maximum permitted weight per axle of locomotives, in long tons	22½	10
Minimum seating space per passenger:		
Width	19½ in.	19½ in.
Floor space	3½ sq. ft.	3½ sq. ft.
Capacity	25 cu. ft.	25 cu. ft.
Standard ballast (stone) per foot of track	6 cu. ft	3 cu. ft.
Cost per tie	$1.46	$0.56
Number of locomotives	253	238
Number of passenger vehicles	750	844
Number of freight vehicles	5 498	4 722
Number of stations on the line (including block cabins outside station limits)	152	209
Number of stations interlocked (including block cabins outside station limits)	69	24

TABLE 32.—PASSENGERS AND PRINCIPAL COMMODITIES CARRIED PER YEAR. (STATISTICS ARE NOT KEPT SEPARATELY FOR EACH SECTION.)

Tons are long tons of 2 240 lb.

Number of passengers	32 975 300
Fibers, raw (mostly loose or not fully pressed), in long tons	1 136 000
Coal, stone, etc	1 107 000
Grain (including flour) and seeds	570 000
Miscellaneous and general merchandise	580 000
Oils, drugs, chemicals, and spices	338 000
Metals and their ores	128 000
Fodder	114 000
Timber, wrought and unwrought	113 000
Salt	106 000
Sugar	84 000
Fibers, spun or woven	80 000
Railway material	72 000

The writer considers that the figures in Tables 32, 33, and 34 prove conclusively that the statement that a narrow-gauge line is more expensive to work than a broad-gauge is not of general application, but needs qualification, depending on the circumstances obtaining in each case. The writer admits the inferiority of a narrow-gauge to broader gauges in one particular only: "Lack of speed." If the speed on the narrow-gauge be sufficiently reduced below that on the broader

Mr. Osborne.

TABLE 33.—Operating Statistics.

Passenger Services.	5 ft. 6-in. section.	3 ft. 3⅜-in. section.
Passenger train-miles per year per mile of line	5 139	2 284
Earnings per passenger train per mile (includes mail and express)	$0.99	$0.85
Cost of working a passenger train 1 mile (includes mail and express)	0.58	0.42
Receipts per passenger mile	0.0045	0.0043
Expenses per passenger mile	0.0026	0.0021
Average number of passengers in a train	184	168
Average weight of a passenger train, in long tons	264½	174½
Coal per passenger engine per mile, in pounds	58	39½
Average speed of passenger trains, including stops, in miles per hour	21¼	17⅛
Maximum speed of any passenger train, including stops, in miles per hour	35	25
Freight Services.		
Freight train-miles per year per mile of line	3 482	1 583
Earnings per freight train per mile	$2.10	$1.35
Cost of working a freight train 1 mile	1.22	0.82½
Receipts per freight ton-mile, in long tons	0.0101	0.0107
Cost of carrying 1 ton of freight 1 mile, in long tons	0.0064	0.0065
Average load of freight in a train, in long tons	183	121½
Average gross weight of a freight train, in long tons	551½	352¼
Coal per freight engine per mile, in pounds	87½	62¼
Average through speed of a freight train, in miles per hour	14	12⅜
Ratio of paying freight to total capacity hauled	34.44%	34.35%

Note.—The writer submits these figures for the purposes of comparison only, and not as the best results obtainable on either a broad-gauge or a meter-gauge.

TABLE 34.—General Statistics.

	5 ft. 6-in. section.	3 ft. 3⅜-in. section.
Cost of maintenance of track, works, and stations, per year per mile of track	$1 072	$462
Cost of maintenance of track, works, and stations, per year per train-mile	0.211	0.140
Fuel and all locomotive expenses (including wages and renewals), per train-mile	0.198	0.174
Car expenses, renewals, cleaning, oiling, etc., per train-mile	0.076	0.58
All other operating expenses, including station staff, per train-mile	0.194	0.116
Average cost per long ton of coal at engine shed	1.85	2.87
General charges: Audit, stores, medical, police, etc., per train-mile (not separated)	$0.055	.....
Taxes, legal expenses, claims, payments to other lines, etc., ratio to gross earnings (not separated)	5.85%	.....
Average miles run per engine per day	73¼	67¾
Ratio of working expenses to gross earnings	60%	56%
Ratio of net earnings to total investment	5⅛%	5⅛%

Note.—The writer submits these figures for purposes of comparison only, and not as the best results obtainable on either a broad-gauge or a meter-gauge.

Mr. Osborne.

gauge, all ill effects of curvature, stability, track stresses, maintenance, etc., are reduced to the level of the broader gauge, but it follows, partly as a result of this lack of speed, that increasing traffic will overtop the capacity of a narrow-gauge, single line and demand further capital expenditure on doubling, conversion, or other means to increase its capacity, sooner than it will in the case of a single line of the broader gauge.

In the particular case with reference to which the writer has given statistics, he considers that extensions on the meter-gauge were a mistake, not on account of any inherent defect of the meter-gauge itself, but because of the difficulties arising from the break of gauge. The cost of extending on the broad-gauge would probably not have involved an additional expenditure of more than $2 500 per mile, against which would have been the saving in rolling stock detained at transhipment junctions and the cost of transhipment terminals, probably sufficient in themselves to wipe out the whole $2 500 and leave the system to the good, as an operating proposition, by the absence of transhipment costs and the restriction to the development of traffic resulting from delay, loss, and damage to goods at the transhipment junctions.

If the system in question had been isolated, the meter-gauge over the whole system would probably have been as advantageous as the broad-gauge over the whole system; nor is it improbable that a 4 ft. 8½-in. gauge, with standards of construction similar to those of the existing gauges, would have obtained similar results. However, the question of the extensions and their gauge did not arise until the broad-gauge section adjacent to the port had been in operation many years, and the acceptance of the meter-gauge for the whole system was impossible for the following reasons:

1.—The lines which now comprise the system had not been brought under one agency at the time the meter-gauge was commenced, and the then diverse interests rendered impossible a complete system on that gauge.

2.—The broad-gauge was in existence, and its conversion would have been an unjustifiable expense.

3.—The port authorities have always very rightly opposed the entrance of mixed gauges to their docks, jetties, and warehouses.

This case is in some respects similar to the problem the author describes in the Argentine, and the writer holds that the correct solution would have been extension by lines of light construction on the 5 ft. 6-in. gauge, and is so far in agreement with the author's solution for the Argentine alone, namely, gradual conversion to 5 ft. 6-in.

Mr. Osborne.

There is considerable difference, however, between the selection of gauge for new lines and the question of converting existing lines to that gauge. In the first case, the extra expense amounts to little; in the second, it is a very important factor, and there must be considerable saving in the cost of operation to justify it. To the writer the solution appears to be: first, the construction of all future lines to the 5 ft. 6-in. gauge, then the conversion to broad-gauge of the more important narrow-gauge main lines, and afterward the gradual conversion of the less important narrow-gauge branch lines.

The writer, however, is not in accord with the author in his selection of the 4 ft. 8½-in. gauge for all lines in South America other than existing broad-gauge lines in the Argentine, which are to be left as they are.

It is not conceivable to the writer that the efficient, important, and financially strong broad-gauge companies of the Argentine, bound together with mutually friendly interests, will consent to remain as they are, and inactive, while they are being isolated and attacked by the 4 ft. 8½-in. gauge, and thus forced to convert to that gauge. It is much more likely that they will successfully seek to preserve their integrity by extensions opening up new territory, and then, on the Argentine will be thrown all the disablements of a mixed gauge which, in the writer's experience, is much more detrimental to the working of a railroad system as an efficient transportation machine than is the mere question of gauge, provided the same gauge be adhered to throughout. If the possibility (which the writer doubts) of a single gauge for South America be admitted, it should be either 5 ft. 6-in. or 3 ft. 3⅜-in., as the majority of the existing mileage is of those gauges.

The author's selection of a 4 ft. 8½-in. gauge for the whole of South America appears to be a compromise between the existing broad and narrow gauges, and based largely on the assumptions that the results obtained on the 4 ft. 8½-in. gauge of the United States and Canada show their railway systems to be the most efficient in existence, and that this efficiency is due, largely, if not entirely, to their gauge.

The writer, being familiar with the working of two large systems: one a 5 ft. 6-in. system which carries 200 long tons of freight 1 mile at a charge of $1.00 and pays 10% on the investment, the other a meter-gauge system, with only one-sixth the freight traffic density of the former line, which carries 111 long tons of freight 1 mile at a charge of $1.00 and pays 8⅓% on the investment, is inclined to question the first assumption, and, as to the second, without disparagement to those of faith and vision who found in a railway of 4 ft. 8½-in. (the then narrow) gauge an instrument for opening up the interior of the North American continent, or to those whose energy and resource-

fulness have enabled this gauge to cope with present traffic conditions and give the results to-day obtained, the writer's experience is that, under conditions now obtaining in this portion of North America, the 4 ft. 8½-in. gauge is a mistake, and that if the gauge were 5 ft. 6-in. the country would now be better served, and for reasons similar to those given by the author in casting the narrow gauge in favor of a broader one. Mr. Osborne.

The forces which have impelled the 4 ft. 8½-in. gauge in North America to economize by increasing the train load and so allowing revenue-ton-miles to increase while reducing revenue-train-miles are world wide, and where the 5 ft. 6-in., meter and other gauges have a live management, they affect them in the same way as they have affected the North American 4 ft. 8½-in. gauge, and South America will gain nothing that she would not otherwise receive along these lines by tearing up her existing 5 ft. 6-in. and 3 ft. 3⅜-in. gauges to replace them by 4 ft. 8½-in.

If the conditions and density of traffic in the area under discussion (Bahia Blanca to north of Rio) are ever likely to approach the conditions and density of traffic of the railways of the United States and Canada, then the extension of the Argentine 5 ft. 6-in. is undoubtedly the gauge that should be made universal.

The writer doubts whether such will ever be the case. There may be considerable similarity between conditions in the southern part of the United States and the southern part of this area, but at their northern extremities one is in the Tropical and the other is in the North Temperate Zone. So far as the writer's experience goes, the inhabitants of a tropical climate do not develop the vigor and capacity for intense effort that lead one to suppose they will ever develop a commerce sufficient to require and justify the railway facilities given in Northern Europe and the northern part of North America. The development of the meter-gauge in the tropical and the broad-gauge in the temperate portion of the area under consideration is not improbably an adjustment to the economic needs of each area, and the writer is inclined to look for the economic and economical development of these areas and their railways along the existing majority gauges, and would endeavor to consolidate the northern lines on the meter- and the southern lines, with the Argentine lines, on the broad-gauge, the dividing line between the gauges, in the absence of political and military considerations, being the traffic-shed between areas tributary to the ports of Buenos Aires and Rio, across which but little traffic would pass.

The writer's experience is that all gauges are good and capable of efficient operation where the standard to which the line is constructed is suitable to the character of the traffic to be moved, but that mixed

Mr. Osborne. gauges and breaks of gauge are an unmitigated evil. In the situation disclosed by the author, the needs would be met by preserving both the 5 ft. 6-in. and 3 ft. 3⅜-in. gauges, which comprise about 80% of the existing railway mileage, as each gauge could be confined to a definite area where the disabilities which arise from a break of gauge on a line of large through traffic would not occur.

THE POSSIBILITIES IN BRIDGE CONSTRUCTION BY THE USE OF HIGH-ALLOY STEELS.

Discussion.*

BY MESSRS. M. SÉJOURNÉ AND GEORGE L. NORRIS.

Mr. Séjourné.

M. SÉJOURNÉ, ESQ.† (by letter).—The writer takes great interest in the problem of the use of steels of high elastic limit for the construction of bridges, and would second the author's efforts to obtain in France—at least for large works—the use of a different kind of steel from that which is now specified, and having the following characteristics:‡

$R = 42$ kg. per sq. mm.

$E = 24$ kg. per sq. mm.

$A = 25\%$ in a standard length, $L = \sqrt{66.67\ S}$

In France it is not usual to construct such great bridges as in America; consequently, the use of steels of high resistance is not as necessary, and the French steel works hesitate to supply themselves with tools for producing in great quantities steels which they are not sure of selling.

The writer is at present engaged in designing a large metal bridge over the Durance, the longest span being 121 m. (397 ft.). On account of the importance of this work, one of the largest steel works in France was requested to quote prices for furnishing carbon steel having the following characteristics:

$R > 50$ kg. $\quad E > 27$ kg. $\quad A = 20$ per cent.

The steel works replied that it would agree to these specifications, provided that an increase in price of 1 Franc per 100 kg. more than for ordinary 42-kg. steel was allowed, but without impact test.

---

* Continued from August, 1914, *Proceedings*.

† Ingénieur en Chef du Service, Chemins de Fer de Paris à Lyon et à la Mediterranée.

‡ It will be noted that these characteristics differ from those given to the author and reproduced by him in his article in *Le Génie Civil*, No. 15, August 7th, 1909.

Mr. Séjourné. In using steels of high elastic limit it seems to the writer to be indispensable to have all the necessary guaranties with reference to its brittleness, and to have recourse, for that, to methods even more stringent than those now used for 42-kg. steel.*

Although French steel works allow tests for brittleness for high-priced special steels, they are generally opposed to them for steels of ordinary make designed for bridges and metal frameworks. These conditions will perhaps be bettered, thanks to developments in the manufacture of steel due to the electric furnace, which produces a material that is not brittle because it is pure. Unfortunately, its price is still too high.

The writer commends the author's endeavors to discover a constituent alloy of great tensile strength, high elastic limit, and of reasonable price. The problem is doubtless difficult to solve, but it is not beyond the science and ingenuity of American engineers, and it is hoped that the author's researches and tests may result in the desired metal.

Mr. Norris. GEORGE L. NORRIS, ESQ.† (by letter).—The author has shown the great advantages to be derived in bridge construction, especially for long spans, by the use of steel with high elastic limit. To obtain the high elastic limits which he mentions—60 000 to 100 000 lb. per sq. in.—it will be necessary to use alloy steels.

With alloy steel it is entirely feasible to obtain elastic limits of from 90 000 to 100 000 lb. by heat treatment, and even also in the condition as rolled, but this, of necessity, would increase considerably the difficulties of shop manipulation. In the condition as rolled, the alloy steels would naturally be too variable in hardness for safe use.

In the case of nickel steel, in order to attain an elastic limit of 60 000 lb. or more, it is necessary to increase the percentage of carbon to undesirable limits.

To produce steel having an elastic limit approaching 100 000 lb., and workable under ordinary shop manipulations, the writer believes that recourse will be had to the use of vanadium alone, or with some other metal such as chromium in the steel. Vanadium is undoubtedly the element which, together with carbon, acts with the greatest intensity in improving alloys of iron, that is, in very small percentages. The quantity of vanadium generally alloyed with steel, excepting tool steels, is about 0.15 or 0.20 per cent. The price of vanadium has been reduced 60% within the past 3 years, and it is now low enough to

* In reference to the information given to the author, and reproduced by him in his article in *Le Génie Civil* (August 7th, 1909), it is said that the specifications of the French railroads "do not require impact tests, which is greatly to be regretted." This is true, but the writer does not make use of these specifications in his office, and for 12 years he has required such tests on all rolled steel.

† Metallurgical Engr., American Vanadium Co., Pittsburgh, Pa.

bring it within consideration for use in steel for eye-bars and other parts of long-span bridges. Mr. Norris.

Vanadium has generally been used in combination with chromium, although when used with nickel or nickel and chromium it gives greatly increased physical properties; these latter combinations are naturally more expensive. Added to simple carbon steel, especially if the percentage of manganese is more than 0.60%, it gives an increase of about 40% in the elastic limit and about 20% in the tensile strength, with practically the same or even greater ductility.

What is known as Type "A" chrome vanadium steel will fulfill the requirements of high elastic limit and be workable under shop manipulations. The cost of this steel would be only slightly in excess of that of 3½% nickel steel. Its chemical range would be:

Carbon	0.17 to 0.27	per cent.
Manganese	0.40 to 0.60	" "
Chromium	0.60 to 0.90	" "
Phosphorus, not more than	0.05	" "
Sulphur, not more than	0.05	" "
Vanadium, not less than	0.15	" "

As rolled, in plates, shapes, and bars, this steel would have approximately the following properties:

Elastic limit	Tensile strength.	Elongation in 8 in.	Reduction of area.
60 000	85 000	12%	45%
to	to	to	to
80 000 lb.	110 000 lb.	20%	60%

By the simple operation of heating to 1 100 or 1 150° Fahr., any irregularities in hardness and strength, due to variation in rolling temperatures or uneven cooling, can be removed without appreciably decreasing the elastic limit and tensile strength, and, at the same time, increasing the ductility. This operation would not be an expensive one, and experience might show that it would be unnecessary for this grade of steel.

Type "A" chrome vanadium steel can be sheared, punched, reamed, bent, etc., without any considerable increase of shop manipulations.

Much higher elastic limit and tensile strength can be obtained from this steel by heat treatment, quenching and tempering, but this would increase the shop manipulations very materially, necessitating drilling instead of punching and reaming. It would also add materially to the cost. Any bends would have to be made before heat treatment.

Rather than heat-treat steel of this type, it would be preferable to attain elastic limits of 80 000 to 100 000 lb. by increasing the carbon percentage, and normalize the steel by heating to 1 100 or 1 150° Fahr.

Mr. Norris.

The range in chemical composition for this grade would be:

Carbon	0.30	to 0.40	per cent.
Manganese	0.40	to 0.60	" "
Chromium	0.60	to 0.90	" "
Phosphorus, not more than	0.05	"	"
Sulphur, not more than	0.05	"	"
Vanadium, not less than	0.15	"	"

Plates $\frac{1}{2}$ in. thick, in the upper range of this composition, have shown the following physical properties:

Elastic limit.	Tensile strength.	Elongation in 2 in.	Reduction of area.
125 000 lb.	145 000 lb.	18%	58%

These plates could be punched and sheared as rolled, but it would be advisable no doubt to normalize, as before described, and also to drill rather than to punch the holes.

Plates $\frac{5}{8}$ in. thick, at the low range of this composition, have shown the following physical properties:

Elastic limit.	Tensile strength.	Elongation in 2 in.	Reduction of area.
83 000 lb.	116 000 lb.	20%	45%

Normalized, this grade of steel should give, in plates and shapes, the following physical properties:

Elastic limit.	Tensile strength.	Elongation in 8 in.	Reduction of area.
75 000 to 100 000 lb.	100 000 to 125 000 lb.	More than 12%	More than 50%

The cost of these chrome vanadium steels would be about 3 cents per lb. more than for ordinary carbon steel.

The writer believes that a simple carbon vanadium steel would prove commercially more attractive than the vanadium steels containing chromium or nickel or both. It is possible to obtain a very material increase in elastic limit by the addition of vanadium to a simple carbon steel, and such steels can be manipulated almost, if not quite, as readily as ordinary carbon steel.

Tests from $1\frac{1}{16}$-in., round, rolled bars of acid open-hearth casting steel of the following composition give a very good idea of what can be expected from this type of steel and how it compares with simple carbon acid open-hearth casting steel:

Carbon	0.26	to 0.27	per cent.
Manganese	0.60	to 0.64	" "
Silicon	0.25	to 0.25	" "
Vanadium	0.21	to 0.00	" "
Phosphorus, less than	0.05	to 0.05	" "
Sulphur, less than	0.05	to 0.05	" "

Mr. Norris.

Elastic limit	70 000	to 56 000	lb.
Tensile strength	88 000	to 72 000	"
Elongation in 2 in.	28.5	to 34	per cent.
Reduction of area	57.5	to 58	" "

From these and other tests, it would seem feasible to specify as follows, for this type of steel:

Carbon	0.20	to 0.30	per cent.
Manganese	0.60	to 0.80	" "
Phosphorus, not more than		0.05	" "
Sulphur, not more than		0.05	" "
Vanadium, not less than		0.15	" "

Elastic limit	50 000	to 70 000	lb.
Tensile strength	80 000	to 100 000	"
Elongation in 2 in., more than		20	per cent.
Reduction of area, more than		45	" "

The additional cost of vanadium steel of this grade over that of ordinary carbon steel should not be more than 1 cent per lb., and very likely would be less.

For built-up members of vanadium steel, the writer believes that vanadium steel rivets should be used, in order to utilize more fully than would be otherwise possible the high physical qualities of the vanadium steel shapes and plates. The rivets could be either of chrome vanadium steel or simple carbon vanadium steel. The composition for chrome vanadium steel rivets should be:

Carbon	0.15	to 0.20	per cent.
Manganese	0.30	to 0.50	" "
Chromium	0.40	to 0.60	" "
Phosphorus, not more than		0.05	" "
Sulphur, not more than		0.05	" "
Vanadium, not less than		0.15	" "

This steel, as rolled in rounds, would have the following properties:

Elastic limit.	Tensile strength.	Elongation in 8 in.	Reduction of area.
50 000 to 65 000 lb.	70 000 to 90 000 lb.	More than 18%	More than 50%

Single and double shear tests of rivets of steel of this type show:

For single shear		20	per cent.
For double shear		30	" "

greater than for ordinary rivets with a tensile strength of 55 000 lb.

Mr. Norris.

The simple carbon vanadium steel should have a chemical range of:

Carbon	0.15 to 0.20 per cent.
Manganese	0.60 to 0.80 " "
Phosphorus, not more than	0.05 " "
Sulphur, not more than	0.05 " "
Vanadium, not less than	0.15 " "

This steel, as rolled in rounds, would have the following properties:

Elastic limit.	Tensile strength.	Elongation in 8 in.	Reduction of area.
40 000 to 55 000 lb.	65 000 to 85 000 lb.	More than 18%	More than 50%

There should be no difficulty in driving rivets of either of these types of steel.

In the case of eye-bars, possibly the conditions are more favorable for the use of alloy steels than for built-up members. They can be more readily and advantageously heat-treated to develop high elastic limits.

In 1909 a number of tests were made of full-sized eye-bars, heat-treated, of chrome vanadium and chrome nickel vanadium steel. These eye-bars were made from bars 14 by 2 in., had 34-in. heads with 12-in. pin-holes, and were 25½ ft. long over the pin-holes.

The chrome vanadium steel bars experimented with were too high in carbon, and the results obtained for elongation in 20 ft. were not quite as good as in the case of the bars from the chrome nickel vanadium steel. Tests from this latter steel gave results ranging as follows, depending on the drawback or annealing temperature after quenching:

	No. 1.	No. 2.
Elastic limit	63 280 lb.	80 480 lb.
Tensile strength	93 500 "	99 800 "
Elongation, 12 in.	35 per cent.	32.5 per cent.
Elongation, 20 ft.	14.2 " "	7.9 " "
Reduction of area	50.8 " "	52.3 " "

Tests on 2 by ½-in. specimens turned up from the disks cut out in machining the eyes check the elastic limit and the tensile strength obtained from the full-sized bar very well. A test from the eye disk of Bar No. 2 showed:

Elastic limit	83 040 lb.
Tensile strength	94 140 "
Elongation, 2 in.	25 per cent.
Reduction of area	71.9 " "

Mr. Norris.

The chemical composition of this steel was approximately:

Carbon	0.25 per cent.
Chromium	0.90 " "
Nickel	1.20 " "
Vanadium	0.17 " "

Based on these tests, it is perfectly feasible to specify as follows for heat-treated eye-bars of chrome vanadium or chrome nickel vanadium steel:

Elastic limit	65 000 to 80 000 lb.
Tensile strength	85 000 to 105 000 "
Elongation in 2 in.	20 per cent.
Reduction of area	50 " "

The cost of heat treatment for eye-bars would probably be from ¼ to ⅜ cents per lb. The cost per pound of the chrome vanadium or chrome nickel vanadium steel would be about 3 cents more than that for carbon steel.

The writer believes that eye-bars made from simple carbon vanadium steel of the following composition, either heat-treated, quenched and annealed, or normalized, heating to about 1 100 or 1 150° Fahr., after the heads have been forged, will give elastic limits approaching those of the more expensive chrome or chrome nickel vanadium steels:

Heat-treated or normalized:
Chemical composition.

Carbon	0.30 to 0.40 per cent.
Manganese	0.60 to 0.80 " "
Phosphorus, not more than	0.05 " "
Sulphur, " " "	0.05 " "
Vanadium, not less than	0.15 " "

Physical properties.

Elastic limit	60 000 to 75 000 lb.
Tensile strength	85 000 to 100 000 "
Elongation in 2 in., more than	18 per cent.
Reduction of area, more than	45 " "

The writer has given considerable attention to simple carbon vanadium steel containing from 0.60 to 0.80% of manganese. This steel will be the commercial or every-day vanadium steel of the immediate future. It is much cheaper than the vanadium steels containing chrome or nickel. It is at least 40% better than simple carbon steel of otherwise the same composition, and is bound to be used extensively in the near future for rails, general and locomotive forgings, and special structural purposes. It presents no especial difficulties in manufacture over simple steel.

Mr. Norris.

The quantity of vanadium which remains in the steel is about 80% of that added. It is very evenly distributed. No instances of segregation are known, and it has a strong influence in overcoming the segregation of other elements, particularly carbon.

Vanadium will readily alloy with nickel, and better results can be obtained from a 2% nickel vanadium steel than from a 3½% straight nickel steel of the same carbon content.

There would be absolutely no advantage gained in the use of titanium with vanadium. Vanadium is an alloying metal and is used as such, not as a scavenger or deoxidizer. It is only the vanadium which alloys with the steel that can be considered as influencing the quality of the latter. Titanium has a little merit as a deoxidizer over silicon or aluminum, and its action is apparently a surface reaction. It is a question whether the observable reaction, when evident, is not with the highly oxidizable basic slag with which it comes in contact, or even with the atmosphere.

THE DETERMINATION OF SAFE YIELD OF UNDERGROUND RESERVOIRS OF THE CLOSED-BASIN TYPE.

Discussion.*

BY MESSRS. O. E. MEINZER AND KENNETH ALLEN.

Mr. Meinzer.

O. E. MEINZER, ESQ.† (by letter).—Mr. Lee's investigation in Owens Valley is a valuable contribution to the study of ground-water. The demand for irrigation supplies and the increasing availability of ground-water because of improved irrigation and cultural methods and decreased pumping costs have created a need for information as to the magnitude of ground-water supplies, the question being primarily not as to the quantity stored in the earth but as to the annual recharge or safe yield. Any contribution to the methods for estimating the annual supplies of ground-water, therefore, is especially valuable at this time. Four principal methods or groups of methods, which may be called the percolation, underflow, water-level, and evaporation methods, have been used. The first consists in estimating the quantity of water that percolates into an underground reservoir from streams or other surface sources; the second in measuring the flow of ground-water at selected cross-sections, being similar in principle to the gauging of surface streams; the third in observing fluctuations in the water-table, which represent filling or emptying of the underground reservoir; and the fourth in measuring the discharge of ground-water through evaporation from soil and plants. All these methods are laborious and difficult to apply, and none of them can be expected to produce precise results, but they are valuable, nevertheless, because they give some tangible basis for estimating ground-water supplies.

* Continued from August, 1914, *Proceedings*.

† In Charge, Ground-Water Div., Water Resources Branch, U. S. Geological Survey.

Mr. Meinzer.

In the Owens Valley investigation, Mr. Lee used both percolation and evaporation methods, his distinctive contribution consisting in developing the latter method and placing it on a quantitative basis.

The evaporation method gives promise of extensive applicability because a large number of the ground-water reservoirs that will be developed for irrigation, discharge wholly or chiefly by evaporation. Débris-filled basins are the most characteristic features of the United States west of the Rocky Mountains. They are of two types: Those which discharge ground-water through springs and evaporation areas, as described by Mr. Lee, and those which do not. In the geologic literature dealing with these basins this fundamental distinction is generally ignored, and the characteristics of the evaporation areas are commonly accounted for by the wholly inadequate explanation of evaporation of surface waters. The process of ground-water evaporation, however, has been clearly stated by F. H. Newell,* M. Am. Soc. C. E., in one of the earliest papers on water resources published by the United States Geological Survey, and in recent ground-water investigations the significance of evaporation areas has come to be clearly recognized. Mr. Lee has furnished experimental data showing that these areas are quantitatively important in discharging ground-water.

Work in numerous débris-filled basins has shown that it is entirely feasible to ascertain from surface indications whether or not a basin is discharging ground-water by evaporation. The evaporation areas in some of the basins have been mapped with nearly the same accuracy that is possible in mapping geologic formations. The three criteria, all of which are suggested in the paper, are (1) moisture of the soil; (2) soluble salts at the surface; and (3) native plants that feed on ground-water. Experience is necessary, of course, for a proper application of these criteria, but they are trustworthy when rightly used. Moreover, they can be tested at any time by making a shallow boring, for ground-water evaporation takes place only where the water-table is near the surface. In a recent ground-water survey of the Big Smoky Valley, Nevada, the relations between the vegetation zones and the depth to the water-table were found to be very similar to those stated by Mr. Lee (page 867),† but the plant species that serve as indicators of ground-water are not the same in different parts of the West. The mapping of evaporation areas is important not only because these areas make possible estimates of the annual supplies, but also because they reveal the base level of the ground-water surface, and thus make possible a forecast of the depth to water in other parts of the basins in which they occur.

Mr. Lee's first conclusion (page 818)† is open to criticism in being too general. On the basis of his investigation in the Owens Valley

* "Water Supply for Irrigation," U. S. Geol. Survey, 13th Annual Rept., Pt. 3, p. 29, 1893

† *Proceedings*, Am. Soc. C. E., for April, 1914.

Mr. Meinzer.

he concludes that the underground reservoirs of California and the Southwest are water-tight rock basins. Many of the débris-filled basins of the Southwest, however, even those comparatively well enclosed by mountains, have no ground-water discharge through springs, evaporation, or transpiration, and it must be assumed that the supplies which they undoubtedly receive are disposed of entirely through rock absorption or underground channels of escape. Some of the reservoirs which discharge water by springs, soil evaporation, and transpiration, no doubt also suffer losses through rock absorption or leakage. In this respect each basin forms a separate problem, the amount of underground loss depending on the stratigraphy and structure as well as the topography. It should be noted that such loss, if heavy, will make the estimates obtained by the percolation method too large and may make those obtained by the evaporation method too small. One of the sources of the public supply of Goldfield, Nev., has consisted of wells in a closed débris-filled basin which has no discharge by evaporation. Such a basin will yield some water even though it has no natural discharge through springs, evaporation, and transpiration, but its yield will be less than the quantity that percolates from surface sources to the water-table.

The writer was disappointed in not finding in Mr. Lee's paper a more definite discussion of the probable percentage of accuracy of his results, as such a discussion would have added greatly to the value of the paper. Mr. Lee's analyses both of recharge and of loss are excellent, but in order to reach quantitative conclusions he was obliged to make numerous assumptions in respect to both. Although these assumptions were, the writer believes, made carefully and with good judgment, they must have introduced considerable errors into the computations. As assumptions enter into both estimates, neither one can be regarded as a check on the other. The fact that the two estimates are of the same magnitude justifies added confidence in the general results, but the fact that they differ by less than 4% does not indicate, of course, that the percentage of error is within 4%, and can hardly be considered a confirmation of the reliability of the data and the correctness of the assumptions in either computation (page 881)*.

The four sources of percolation are given as (1) direct precipitation; (2) stream flow; (3) irrigation; and (4) flood-water in the valley floor. It is assumed that the high mountain areas shed all precipitation except that which is lost by evaporation; that on the more elevated parts of the intermediate mountain slope 75% of the precipitation, and on the lower parts 70, 65, and 60%, respectively, join the underground supply; that the contributions to the underground supply on the outwash slopes range, according to zones, from 0 to 60%, making an average of 16%; and that the contribution on the valley floor is 4 sec-ft. All these assumptions are based on care-

*Proceedings, Am. Soc. C. E., for April, 1914.

Mr. Meinzer.

ful, general observations, but are of course only approximations and liable to large errors. Moreover, assumptions are involved as to the areas belonging to the various zones and the amount of precipitation in each (page 875)*. Several assumptions are also made in the estimate of recharge from stream channels, in the conclusion that 50% of the irrigation water is added to the underground supply, and in the estimate of the contributions made by the flood-waters.

The writer agrees with Mr. Lee that the discharge from the underground reservoir can be determined more accurately than the percolation into it, but the methods of estimating discharge also involve a number of elements of uncertainty. If the writer understands rightly the author's discussion of the discharge from irrigated land, the 50%, or 18 sec-ft., of irrigation water discharged by evaporation and transpiration (page 872)* is the portion that was not added to the underground supply (page 881)* and, therefore, should not be included with the discharge from this supply.

The largest element in ground-water discharge is that of evaporation and transpiration from uncultivated land. It is on this question that Mr. Lee has made his most important contribution, and that part of his paper dealing with this phase of the subject deserves, therefore, the most critical consideration. Some of the factors that enter into this estimate were determined by experiment and others by field survey. Experimental errors were involved in the difference between natural and artificially packed soils, in the difference between the vegetation in Nature and in soil tanks (pages 855, 856, 861, and 862),* in uncertainties as to the actual water-level in the tanks (pages 852 and 853),* and in the unavoidable fluctuations in the water-levels in each tank (Tables 9 to 14, inclusive). These experimental errors are represented in part only in the diagrams in Fig. 10. In the summer diagram, which is the more important one, the results from Tanks Nos. 5, 6, and 7 fall nearly on the curve used by Mr. Lee in his calculations, the result from Tank No. 4 being more than 20% too low, that of Tank No. 3 more than 20% too high, and that of Tank No. 2 nearly 40% too low. It should be noted, however, that although these results involve large experimental errors, they corroborate each other in a general way and are of great value in furnishing reliable data on the general magnitude of one of the most important processes in ground-water circulation.

In applying the experimental data to the basin under investigation, inaccuracies were involved in the sizes of the areas having specified depths to the water-table, in the fluctuations of the water-table, in difference in the range and rate of capillary rise due to difference in the character of the soil, and in difference in the density of vegetation

* *Proceedings*, Am. Soc. C. E., April, 1914.

and kinds of plants that draw water from the underground reservoir. An error was also involved in the fact that observations covering only 1, 2, or 3 years did not give average evaporation conditions, just as precipitation and stream-gauging data for a period of the same length do not afford reliable averages. With 142 observation wells on the valley floor (page 866),* the error as to the water-table cannot have been large, yet the rate of discharge varies so greatly with small changes in depth of the water-table that even slight inaccuracies in determining one produce appreciable errors in calculating the other. Although the valley floor in that part of Owens Valley investigated by Mr. Lee has relatively uniform conditions, there is luxuriant salt grass in some parts and an entire absence of vegetation in others (page 828),* whereas the experiments did not cover these different conditions. Moreover, no account was taken of the zone having depths to the water-table between 8 and 12 ft., although the greasewood and rabbit brush in this zone probably draw water from the underground reservoir (page 867).* Mr. Meinzer.

The writer agrees with Mr. Lee that the evaporation method is the most feasible one for estimating ground-water recharge in many of the débris-filled basins, especially where there are as yet few developments, but its application is far from being a simple matter. The data which he obtained in Owens Valley have value in making rough estimates of annual recharge in valleys in which the evaporation areas are mapped and reliable observations are made as to the character of the soil and vegetation and the distance to the water-table in the different zones of such areas, but to assure any considerable degree of accuracy for most valleys it will be necessary not only to sink a large number of observation wells and to keep them under observation for one or more years, as was done in Owens Valley, but also to obtain a great deal more information as to the rate of discharge under various conditions of soil and vegetation. The conditions in the evaporation areas of most valleys are far from uniform, the soil ranging from dense clay to coarse sand or gravel, and the vegetation embracing a number of diverse species and being entirely absent over large tracts.

The writer wishes to urge the importance of further investigations along the lines suggested. The lowest parts of many of the closed basins are underlaid by clay cores destitute of vegetation but surrounded by zones of less dense soil in which evaporation and transpiration are active. The dissemination of the soluble salts instead of their concentration at the surface and other conditions lead him to believe that on these clay cores the ground-water discharge is sluggish, but definite tests are needed as to the quantity of discharge and its relation to the distribution of the soluble salts. Among the common native plants (besides the salt grasses) which apparently discharge ground-water, are samphire (*Spirostachys occidentalis*), iodine weed (*Suaeda*),

Proceedings, Am. Soc. C. E., April, 1914.

Mr. Meinzer.

alkaline sacaton (*Sporobolus airoides*), certain species of salt bush (*Atriplex*), big greasewood (*Sarcobatus vermiculatus*), rabbit brush (*Chrysothamnus graveolens*), buffalo berry bush (*Shepherdia*), and mesquite (*Prosopis*). Mesquite does not thrive in the shallow-water areas where the soil is dense and alkaline, but is often dominant in a zone of moderate depth to water surrounding a shallow-water area. It is important to know whether the mesquite actually feeds on ground-water, and if so, from what depth and at what rate it is able to lift this water to the surface.

Mr. Lee's final conclusions (page 887)* sum up admirably the esssential factors in the problem of safe yield. As it is not generally practicable to draw any large part of the ground-water of one segment of a valley to another, a proper distribution of wells is necessary in order to reduce the residual losses to the lowest possible quantity. Overdraft with serious lowering of the water-table may occur in certain segments while evaporation of ground-water contributed by other segments is still in progress on the lowest lands. Such loss can be prevented only by increased withdrawals in the undeveloped segments, and if these segments have little or no land that can be profitably irrigated, the loss may be unavoidable.

Mr. Allen.

KENNETH ALLEN, M. AM. SOC. C. E. (by letter).—Underground water supplies, as well as surface supplies, depend on the rainfall, the catchment area, and the available storage, with its accompanying losses by overflow, leakage, and evaporation; but the problem for the engineer is more difficult in the case of underground supplies, as the true limits of the catchment area, the storage capacity, and the probable amount of the losses mentioned can only be determined approximately after a pretty thorough examination of the sub-surface conditions, that is, the configuration of the permeable strata, their impermeable confines, and their physical characteristics—permeability, etc. In the majority of cases much of this information is inaccessible, and more or less dependence is placed on such collateral evidence as the yield of neighboring wells and the results obtained by sinking test wells.

The limitations imposed by enclosing impervious formations and by sub-surface evaporation are clearly and interestingly presented by the author, and their importance is shown under the conditions discussed. In most well developments, however, evaporation is of minor significance. This is not only on account of greater humidity, but because most supplies percolate through an unenclosed stratum for perhaps many miles and because evaporation from this stratum is usually prevented by the superposition of one or more impervious strata.

* *Proceedings*, Am. Soc. C. E., for April, 1914.

Mr. Allen.

In practice the available yield is subject to further limitations. The water-bearing stratum may consist of an impervious rock containing crevices or fissures due to movements in the earth's crust or water-courses caused by the solvent action of the water itself. The latter are of frequent occurrence in limestone and chalk formations and the former in sandstones and the denser igneous rocks. Fissures occur more frequently near the surface than at great depths, and, as the cost of drilling increases with the depth, deep borings in search of water-bearing fissures are not often profitable. The same money can be spent to better advantage in making several test borings at moderate depth. Although the results of such borings are uncertain, supplies, when obtained from fissures, are often abundant and the wells free from the clogging so often experienced with sand. The yield of a well in sand is directly limited by the porosity of the latter and the available head. In fine sands there is a large loss of head due to percolation near the strainer in order to maintain the necessary flow. This difficulty may be overcome by increasing the length of the strainer if this does not exceed the thickness of the water-bearing stratum, but this is at the expense of a greater first cost as well as an increase in lift due to the fineness of the material. In such cases the loss of head is often reduced by removing the sand about the strainer and filling the pocket with gravel, or else by substituting a larger number of driven well points from 2 to 3 in. in diameter for the large (6 to 12-in.) casing and strainer.

In those cases where the water occurs in a stratum of fine sand of small thickness, the difficulty is further increased. The writer tested a stratum of this kind several years ago with the view of developing a supply of some 5 000 000 gal. daily for a Southern city. Water was found in apparent abundance throughout a large area at a moderate depth, the land was low, covered with forest, not far from a stream of considerable size, and on it were several large springs. On sinking numerous test wells on a line about 4 miles long, however, it was shown that the water-bearing stratum, besides being of a fine sand, was so thin that the cost of developing the desired supply would be prohibitive.

Water supplies found in deep deposits of sand or drift, especially those derived from distant and extensive catchment areas, such as exist south of the great terminal moraine on the south side of Long Island and on the Atlantic Coastal plain from Sandy Hook to Florida, are most favorable for development. Well-known examples are the 1 400-ft. Ponce de Leon well at St. Augustine, said to furnish 10 000 000 gal. daily, and the 1 970-ft. well at Charleston furnishing 1 250 000 gal. daily. On the other hand, a well was bored in 1900-01 at Atlantic City, N. J., to a depth of 2 306 ft. (below the floor of Young's Pier), and although a good supply was found between depths of 780 and 860

Mr. Allen.

ft., in a stratum of sand tapped by numerous wells in the vicinity, the supply sought at the greater depth was not realized, and the well, then the deepest but one along the Atlantic Coast, was abandoned.

About 5 miles inland, the Water Department had a small collecting basin near its pumping station (Fig. 15), in which were driven a number of 4-in. tubes tapping a water-bearing stratum 24 ft. below. Near the basin was a 10-in. well (No. 3) extending to a depth of about 100 ft. to another water-bearing stratum which it was proposed to develop as an additional supply to the extent of 3 000 000 or 4 000 000 gal. daily. The capacity of this well was first tested by erecting over it an old 1 000 000-gal. Worthington pump, which the Department had, and connecting it with a steam line to the boiler plant at the station. During a 6-hour test with a 19-in. vacuum on the suction,

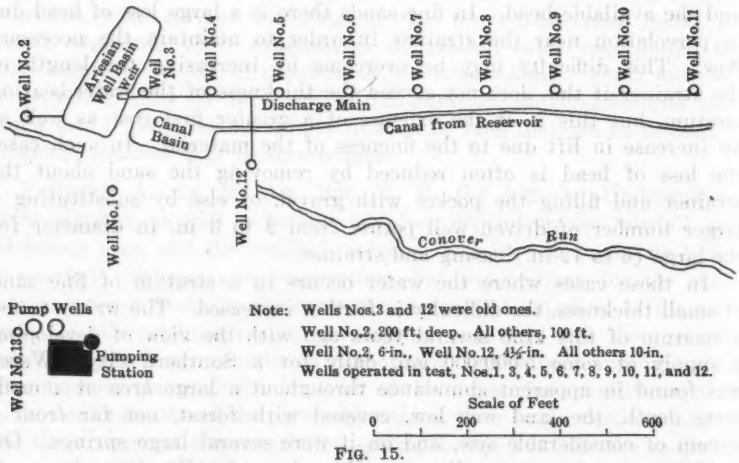

FIG. 15.

the delivery was practically uniform at a rate of 840 000 gal. per day, and as no downward flow was observed in the small tubes in the basin, it was concluded that there was no connection between these two strata. On the strength of this test, ten 10-in. wells, 125 ft. apart, were sunk to a depth of about 100 ft. and a 6-in. well (No. 2) to a still deeper stratum, 200 ft. below the surface. Besides these there were two old wells—the 10-in. well tested with the steam pump and a 4½-in. well (No. 12), both of which were carried to the 100-ft. stratum. The deeper 6-in. well flowed freely at a rate of 66 000 gal. per day and, by use of the air lift, at a rate of 400 000 gal. per day, or about 280 gal. per min. The 10-in. wells on short separate tests produced from 150 to 400 gal. per min. Ten of the 10-in. wells (No. 1 and Nos. 3-11) and the 4½-in. well (No. 12) were then connected with

Mr. Allen.

the compressor and given a 6-hour test. These wells together delivered 846 879 gal., or at a rate of 3 705 492 gal. per day. This was an average of 336 866 gal. per well, or 60% less than the delivery from Well No. 3 when operated alone. Moreover, the average lift in this well during the test was 24.56 ft., though the vacuum gauge on the suction during the earlier separate test indicated a lift of 21 ft. to about the same level. Assuming this well to have produced one-eleventh of the total quantity during the combined test, the effect of interference from the other wells, while operating all eleven at this rate, was to increase the lift by about 3.6 ft. while reducing the output by 60 per cent.

The yield under conditions found along the Coastal Plain region bears little relation to that from underground reservoirs of the closed-basin type described by the author, but somewhat similar conditions are met in the basin of the prehistoric Lake Passaic of Northern New Jersey. Wells in the outlet of this lake, now filled with glacial drift, furnish the water supply for East Orange. When first sunk, several of these 6-in. and 8-in. wells had a natural flow of from 400 to 500 gal. per min.

Above this outlet water-bearing sandstones underlie the ancient lake, but percolation to these beds is cut off on the northwest by the trap dikes forming the Orange or Wachung Mountains and on the southeast by the Palisades of the Hudson. Assuming a general southerly flow, percolation from a distance, therefore, is limited to that from the northeast, the limit in this direction, it is believed, being unknown.

These sandstones, nevertheless, furnish a large number of excellent well supplies in the vicinity of Newark and Paterson, chiefly by means of their numerous fissures.*

Data concerning a large number of these wells, collected by the writer a few years ago, indicate a great variation in the yield. They are commonly from 100 to 500 ft. in depth, and 6 or 8 in. in diameter, and generally furnish from 20 to 200 gal. per min. each, although failures are not infrequent, and several produce as much as 500 gal. per min.

REINFORCED CONCRETE DOCKS: FOREIGN AND AMERICAN STRUCTURES. FAILURES, COSTS, AND GENERAL CONSIDERATIONS.

Discussion.*

By E. G. Walker, Assoc. M. Am. Soc. C. E.

Mr. Walker.

E. G. Walker, Assoc. M. Am. Soc. C. E. (by letter).—At first thought it might appear remarkable that so little progress relatively has been made in the application of reinforced concrete to marine works in the United States; and in certain places in his paper, the author seems to attribute the present state of affairs to a conservatism of ideas on the subject utterly opposed to the general conception of the American progressive spirit. The writer is inclined to differ from this deduction, because he believes that in the United States as elsewhere the form of construction adopted for marine works is the result of economical evolution. A paper† on the piers of New York Harbor, recently presented before the Society, is an admirable illustration of this point, showing as it does in a very conclusive manner that special conditions evolve special types. A consideration of this paper leaves little doubt that the engineers of the Department of Docks and Ferries have arrived, by the judicious use of timber in some parts and reinforced concrete in others, at a type of pier of maximum economy under the conditions prevailing in New York Harbor. These conditions, however, are not comparable with those obtaining in certain teredo-infested waters on the coast of Great Britain, for example, where pitch pine piles will be dangerously eaten away in a few years

* Continued from August, 1914, *Proceedings*.

† "Modern Pier Construction in New York Harbor," by Charles W. Staniford, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 503.

Mr. Walker.

and where even Australian hardwood piles have to be renewed at comparatively short intervals. Although there appear to have been a number of unfortunate experiences in the United States, there is no question that concrete and reinforced concrete can be used successfully for marine works, because engineers have had ample experience in the use of both materials; but there are many locations where it may be more economical to use timber, in spite of its shorter life and other disadvantages. At the present time there is a large quay under construction on the River Tyne, in England, forming the largest item in a $1 000 000 scheme, which will be built of timber throughout. In North America, where timber is so much more easily obtainable than in the United Kingdom, the writer thinks that it will be a long time before it is completely ousted by reinforced concrete.

In many cases in the United Kingdom the application of reinforced concrete to quay and jetty construction has been brought about by economical necessity rather than by ideas of progressiveness *per se*. Most of the waters of the British ports carry teredo, and in many cases no timber but greenheart or jarrah will withstand its ravages. The Hennebique system of "ferro-concrete" construction, introduced into England by the late M. Mouchel, was first applied to sea-works at Southampton and, about the same time, to a jetty in the River Thames, at Purfleet. Both these works are referred to in detail in the paper. The success which attended them probably contributed very materially to the later popularity of reinforced concrete.

In general, under average British conditions, greenheart construction is about as expensive as reinforced concrete, pitch pine being, of course, considerably cheaper than either. Hence, in the absence of special conditions (such, for example, as those at Port Talbot mentioned by the author), pitch pine may be used in places where the marine borers are not too active, whereas in other locations either hardwood or reinforced concrete may be used, according to the local balance of general economy. In connection with this, the proved low maintenance cost of concrete work is a most important factor, and it is significant that in most cases where concrete pile-work has been introduced, its use has been continued.

The remarkable resilience of concrete piles under driving has been a most important factor in the increase in their use, but the writer thinks that the particulars given by the author on page 967* are scarcely applicable to a discussion on pile-work. It is reasonable to suppose that a hollow post of the dimensions given, reinforced with a large number of small rods, will be much more flexible than an ordinary pile, and such is the case. The resilience of piles is best

* *Proceedings*, Am. Soc. C. E., for April, 1914.

Mr. Walker.

exemplified by the treatment that they are able to stand in ordinary use, and particularly in driving. In the early days, the interposition of a special dolly between the pile and the monkey was considered essential, but since it has been found that properly arranged spiral winding is able to withstand all the punishment that the pile-driver can give it, the dolly is no longer used. This, in itself, is quite sufficient proof of the resilience of reinforced concrete piles; and there is plenty of other evidence.

A point which has arisen and which has been much discussed more particularly in connection with marine work in England is the subject of the relative advantages of pre-moulded members and members formed *in situ*. It has been contended that the former method is the better one by reason of its being more convenient, but the writer believes that, except where the special conditions of the case preclude it, it is desirable to build the structure as monolithic as possible. No matter how carefully the work is carried out, it is hardly possible to unite satisfactorily hardened concrete several weeks old with the new concrete that must be put in to form the joint; nor can one get in built-up work the strength obtained by the continuity of the steel from one member to another in monolithic work. The use of additional binding steel at the joints does not fully compensate for this. Advocates of the built-up system put forward the claim that monolithic work may be considerably weakened by the wrong disposition of the reinforcing bars, and that, therefore, it requires considerable and constant supervision; but surely the increased relative importance of the field-work in the case of pre-moulded construction entails quite as much detailed supervision on the job.

SOME PRINCIPLES RELATING TO THE ADMINISTRATION OF STREAMS.

Discussion.*

BY HERBERT E. BELLAMY, ASSOC. M. AM. SOC. C. E.

Mr. Bellamy.

HERBERT E. BELLAMY, ASSOC. M. AM. SOC. C. E. (by letter).—The writer has read this paper with particular interest, not only on account of his familiarity with the subject, having dealt with questions of riparian rights in England, and of his knowledge of the systems in vogue throughout Australia, but because of the comprehensive and lucid manner in which the author has dealt with the whole subject. Indeed, the paper embraces practically every phase relating to the betterment in the administration of streams, so that there is very little, if anything at all, to add. The preamble presents amending principles suggested for adoption impartially, and with which, in every case, the writer cordially agrees. The paper brings together, in a small compass, a great mass of information dealing with the application of the doctrine of riparian rights in many countries, which cannot fail to be of the greatest value in the discussion of the subject by engineers.

Some years ago, when the writer was investigating some so-called riparian rights in connection with a proposed new water supply for a town in England, he was greatly puzzled to know what these rights were. Decisions of the Courts did not help him, because, as the author remarks, if the doctrine of riparian rights were carried into effect rigidly, water could not be diverted from a stream in any way. Several decisions could be quoted to support this latter contention if necessary, but the following brief abstract from a well-known case

*This discussion (of the paper by Clarence T. Johnston, M. Am. Soc. C. E., published in May, 1914, *Proceedings*, and presented at the meeting of September 2d, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Bellamy.

merely serves to show that something more tangible should be substituted for the absurd and diabolical doctrine, as it exists in many places to-day. In the case, Mason *v.* Hill, it was decided as follows:

"A riparian proprietor can have no larger right than he has by nature against those above and below him. Hence the right to have a stream to flow in its natural state without diminution or alteration is an incident to the property in the land through which it passes * * *."

The author points out that the first principle which should be recognized is that of public ownership of streams, lakes, and other bodies of surface water. The writer would also include "all underground supplies." This recognition is the fundamental principle of success of stream administration throughout the Australian States. In the writer's opinion, the second principle, *b*, which the author does not discuss at great length, is the positive safeguarding of the interests of the first user of the waters of a stream as against later comers, even including State or National rights.

As the author mentions that the modern system adopted by Australia merits study, the writer submits the following brief digest of the Water Rights Act of 1912 which is in force in the State of New South Wales.

The Water Rights Act came into force in 1896 and was consolidated in 1902. On November 26th, 1912, assent was given to an Act consolidating the separate Acts relating to Water Rights, Water and Drainage, Drainage Promotion, and Artesian Wells. This Act is administered by the Minister for Public Works. On the passing of the original Act, the right to the use and control of all streams, whether perennial or intermittent, flowing in a natural channel, through or past the land of two or more occupiers, and of all lakes, swamps, lagoons, or other sheets of still water, whether permanent or temporary, situate within or fronting the land of two or more occupiers, passed from the owners or occupiers of the said land and became vested in the Crown; subject, however, to the reservation that the said occupiers shall have the right to use the water on their frontage for domestic or stock purposes, or for gardens up to 5 acres in extent, without the necessity for obtaining a license for any work used solely for those purposes.

Rights granted under the Mining Acts on any public or private statute, are also preserved.

Section 8 provides for the rights of the Crown in respect of works, and Section 9 for the rights of the occupiers to which the Act applies.

The definition of "Work" is comprehensive, and includes any dam, lock, reservoir, weir, flume, race, channel (whether an artificial channel or a natural channel artificially improved), any cutting, tunnel, pipe, sewer, and any machinery and appliances; and "Work to which

this part extends" means work connected with any river or lake flowing through, or past, or situate within the land of two or more occupiers, or with any water flowing in, to, or from, or being in any river or lake flowing or situate as aforesaid, whether such work be for water conservation, irrigation, water supply, or drainage, and whether such work be constructed before or after the commencement of this Act. Mr. Bellamy.

Section 10, and succeeding sections, provide for the granting of licenses to private individuals. Any person being in actual occupation of the site of a proposed work may make application for a license. The application should be forwarded to the Minister for Public Works, who will then advertise its receipt, together with a date and place at which a public inquiry will be held as to the advisability of granting the application. These inquiries are usually held by the local Land Board, and any person affected by the application may attend and give evidence for or against the granting of the application. Any person aggrieved by the finding of the Board may appeal to the Land Appeal Court within 28 days of the date of such finding. The finding of the Board is published in the *Government Gazette,* and, after the expiration of 30 days from the date of publication, the Minister, where the Board recommends the granting of the application, and provided no appeal is pending, shall issue a license for such period, not exceeding 10 years, as he may think fit, subject only to such conditions, if any, as may be embodied in the Board's finding. The applicant is notified by the Minister of the term for which it is intended to grant a license, and the amount of the fee which must be paid before a license can be issued.

Section 13 of the Act provides for joint application by two or more occupiers, as, for instance, persons on opposite sides of a stream who desire to construct a dam.

Section 17 is very important, because it secures to the holder of a license quiet enjoyment, and the sole and exclusive use, of the licensed work as against all persons, including the Crown.

Section 18 provides for a penalty for any alteration of work during currency of a license.

Sections 19 and 20 provide for the carrying out of works by the Crown, the formation of "districts" benefited by such works, the assessment of charges in each and every case for benefits accruing to the properties within the "district", and the payment of charges by the persons benefited. The actual procedure is conducted as follows:

"The Governor notifies by proclamation in the *Government Gazette* a proposal for the construction of a dam, lock, weir, channel or drainage work, as the case may be, to be constructed by the Crown, together with an estimate of cost. This notification is followed by the gazettal

Mr. Bellamy.

of the boundaries of a 'district,' the land within which will, in the opinion of the Local Land Board, be benefited by the construction of the proposed work, and within which water or drainage charges may be levied. It is then necessary that a 'two-thirds majority' of the occupiers, who must also occupy an area exceeding two-thirds of the total area within the proclaimed district, petition the Land Board, on the proper form, to carry out the proposed work. In default of this petition the proposal lapses. On receipt of the petition, the Land Board may report to the Minister, recommending that the work be carried out, and after the expiration of thirty days from receipt of the Board's recommendation, the Minister may carry out the work with funds legally available. On completion of the work, the Land Board, by direction of the Minister, assesses the charges to be paid by each individual occupier, and the aggregate of these charges must not exceed six per cent. on the total cost of the work. The charges commence from the date of completion of the work, which must be advertised in the *Government Gazette*. The assessment takes place in open court, and the persons affected may attend and give evidence on their own behalf. On the petition of persons liable to pay one quarter of the total assessment, the Land Board must make a fresh assessment."

The remaining Sections, 21 to 27, refer to miscellaneous matters such as injuries to works; power of entry; obstructing persons in the performance of duties; recovery of fees, charges, and penalties; appeal; consolidated revenue; and the power to make regulations.

The regulations at present in force provide penalties for pollution, obstruction of or interference with the water in any stream or lake, and for causing trees, or débris of any kind to fall into any stream or lake, and also prescribes the various forms to be used under different sections of the Act.

From a perusal of these Acts,* it will be found that many of the principles advanced by the author have been provided for and are in successful operation in Australia.

The author certainly deserves the thanks of all water engineers for the exhaustive and thorough manner in which he has treated a most delicate and vexed subject.

* Copies of the Water Rights Acts at present in force in three of the Australian States, namely, Act No. 44, 1912, New South Wales; Act No. 2016, 1905, Victoria; and Act No. 25, 1910, Queensland; are on file in the Library of the Society.

THE CONSTRUCTION OF THE KLONDIKE PIPE LINE.

Discussion.*

BY MESSRS. G. B. PILLSBURY AND WALTER S. WHEELER.

Mr. Pillsbury.

G. B. PILLSBURY, M. AM. SOC. C. E. (by letter).—The description in this paper of the frozen soil in the Klondike is most interesting, but should perhaps be supplemented in order to prevent a misconception of the difficulties and possibilities of earthwork in Alaska. The writer was engaged for several years in wagon-road construction throughout the occupied portion of the Territory, and acquired a fairly intimate acquaintance with its frozen ground.

In the interior of Alaska—the area north of the enclosing coastal range—the mean annual temperature is below the freezing point. As the temperature of the ground some feet below the surface must be approximately the mean of the surface temperature, it follows that this ground is, in general, permanently frozen. The underground drainage being thus sealed, the ground-water level is high, and the country is extremely swampy. Deposits of swamp muck, therefore, are very common in the valleys and elsewhere, and they sometimes contain lenses of solid ice several feet in thickness. As the author remarks, when the moss that covers this muck is stripped, its ice content melts under the summer sun. The writer has often seen a narrow ditch quickly enlarge into a wide and deep gully through this action. It is very obvious that if ice is built on, it must be kept frozen, and in order to keep it frozen, its protecting coat of moss must be retained.

* This discussion (of the paper by W. W. Edwards, Assoc. M. Am. Soc. C. E., published in May, 1914, *Proceedings*, and presented at the meeting of September 2d, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Pillsbury.

It by no means follows, however, that all the valleys are covered with muck and ice, any more than all the valleys in more temperate zones are covered with muck and water. Ordinary earth lying below the ground-water, or rather ground-ice, is frozen throughout the summer, and the difficulties of working it, with the general sloppiness of the earthwork accomplished, are similar to those encountered in work in the very early spring in the northern part of the United States. It can be loosened, however, by blasting, and the difficulties in handling are merely those common to water-saturated earth. Earth above the ground-ice level thaws and dries readily, and its working is entirely normal.

The writer has traveled over a railroad near Nome to which the author possibly refers in the latter part of his paper. It was a very light surface road, and had the misfortune to be located, for the greater part of its length, on a frozen swamp. Light ditches had been dug through the moss and turf on each side, and these had gullied out so badly that much of the track had to be shifted to one side. The journey of about 60 miles occupied an entire day, although the passengers escaped the usual upset. The writer, however, does not think that any moral can be drawn from this railroad; a swamp does not afford the best location for a railroad in any country, and this road was merely fortunate enough to find its swamp frozen.

The prediction is ventured that good railroad construction in Alaska will follow standard practice closely, henceforth as well as heretofore. Swamps will be crossed on a fill, as usual. The principal departure from construction elsewhere will be in the matter of unit costs, and these, on account of the short working season and distance from supplies, will be several times greater than on any road in the United States.

Mr. Wheeler.

WALTER S. WHEELER, M. AM. SOC. C. E. (by letter).—Records at Skagway, Alaska, show that during the open season of 1907, the Guggenheims shipped into Dawson more than $5 000 000 worth of freight, a considerable portion of which was material for the Klondike pipe line of the Yukon Gold Company. The freight was landed, from ocean steamships, at the wharf in Skagway, and transhipped, over the White Pass and Yukon Narrow-Gauge Railroad, 111 miles to White Horse, and then by steamer down the Yukon to Dawson. The freight and passenger rates over this road are naturally quite high, as a considerable portion is built through exceedingly mountainous country, and the bulk of travel is confined to the summer, when navigation is open on the Yukon River. The track has a 3.9% grade for about 16 of the first 20 miles out of Skagway, to the famous White Pass, which is about 2 800 ft. above Skagway and mean tide. This portion of the road cost $2 000 000, or an average of $100 000 per

Mr. Wheeler.

mile, and it is said that the road more than paid for itself during the first two years of operation.

Mixed trains leaving Skagway are drawn by four engines distributed equally throughout the same. At a point 8 miles from Skagway, a rock thrown into the river from the track struck the water in 5 sec.

By the "Far North", the writer assumes that the author includes all of Alaska and the adjoining Yukon Territory, and also British Columbia lying directly east of Alaska.

Costs for material, labor, etc., vary considerably for different locations. At the time the Klondike pipe line was constructed, with common labor at $4 per day and board, the Alaska Road Commission was paying $2.50 per day and board on the trail out from Haines Mission, with a working season of 5 months in each location. Machinists were paid $5 per day in Skagway, with extra for overtime, and $1 per hour in Dawson, Yukon Territory, and the adjoining creeks. Cord-wood, the principal item of fuel, cost $5.50 per cord delivered in Skagway, and $15 per cord in Fairbanks, Alaska. Board and room, the best obtainable, could be had in Skagway for $40 per month, while the same class of board and room cost $75 per month in St. Michael, Alaska, and Dawson, Yukon Territory, and $125 in Fairbanks.

The cost of electric light in Skagway was 10 cents per kw-hr., and in Fairbanks, 51 cents. Business telephones cost $5 per month in Skagway, and $20 in Dawson and Fairbanks.

These prices were current about 1907 and 1908, and though some of them have changed from time to time, the writer has given them in order to show that they vary considerably in different locations of the "Far North", and that estimates for construction in the "Interior" are, as a rule, much higher than along the Coast.

A fair grade of coal could be purchased in Skagway for $13 per ton, but, in St. Michael, the writer has paid $25 for coal of the same grade. This coal was all shipped from the United States or from lower British Columbia, while billions of tons of the best bituminous and anthracite are waiting to be mined along the coast of Southern Alaska as soon as the Government sees fit to allow it to be opened up.

At Skagway the temperature seldom falls below zero, but it is not unusual to experience a temperature of —70° Fahr. in midwinter at Dawson, Fairbanks, and Nome, and sometimes —80° Fahr. When the temperature falls below about —40° Fahr., there is never any wind, and, the air being very dry at that temperature, the real danger to life is from exposure when it appears to be warmer than it really is.

In summer, ordinary vegetables are grown in abundance, and wild raspberries, blueberries, cranberries, and currants are plentiful.

An excellent breeding place for mosquitoes is formed below the niggerheads (bunches of coarse wild grass) on the tundra, and during

Mr. Wheeler.

May, June, and July, it is impossible to work on the tundras without the protection of nets and gloves; but August and September are comparatively free from these pests, which are not fever-bearing in the North.

It is impossible to make foundations to any great extent with the peat taken from the tundras, as it will dry out and burn up in the numerous tundra fires during the summer, as mentioned by the author in the case of the Nome Railroad.

In places near fresh and salt water, where suction dredges are available, good foundations can be made by running the discharge pipe so that the material will be deposited on the tundra, provided the water is not so rough as to prevent the dredge from operating. The writer had charge of dredging the St. Michael Canal during the summers of 1908 and 1909, and the material discharged from the pipe line would have made excellent foundations on the tundra, if they had been desired. When carrying on construction near the water, it is well to quarter the men on houseboats anchored well out from shore, so that, while not on duty, they can get some respite from mosquitoes. In this way one can obtain a more efficient working crew.

CALIFORNIA PRACTICE IN HIGHWAY CONSTRUCTION.

Discussion.*

BY MESSRS. ALLEN HOAR AND W. C. HAMMATT.†

Mr. Hoar.

ALLEN HOAR, JUN. AM. SOC. C. E. (by letter).—In Mr. Hammatt's very interesting paper, he has brought out very clearly that in California there is an abundant supply of first-class road material of all kinds, well distributed over the entire State, and that, therefore, poor roads there are inexcusable. The author, however, makes several statements, which, though true, in a sense, must be misleading to those who are not thoroughly familiar with all the conditions. The writer is pleased to note that Mr. Hammatt has spoken so highly of water-bound macadam. This type of pavement when well-drained, laid on a properly prepared sub-grade, and carefully constructed, has still a great deal of usefulness.

Under the heading, "Oiled Macadam," the author says, "A very small proportion of the total area of oiled macadam pavement constructed has been successful." He also says, "even under the best conditions, this pavement has little justification." Now, as a matter of fact, as there has been some success, there is certainly some justification for its use. In the introduction to the paper Mr. Hammatt states that it has been only in the last 5 or 6 years that any real road construction has been undertaken in California, but that a great deal of graveling and oiling had been done as a temporary improvement. Such is the case, the first practice of oiling being merely to afford

*This discussion (of the paper by W. C. Hammatt, M. Am. Soc. C. E., published in April, 1914, *Proceedings*, and presented at the meeting of May 20th, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

†Author's closure.

Mr. Hoar. a temporary relief from the dust nuisance and to protect earth and gravel roads from ravages by heavy rain storms. Observation of the results obtained by this treatment led to the adoption of this material in road construction, and finally to the present perfected type of bituminous macadam. In making so broad a statement, that only a very small proportion of the oiled macadam roads has been successful, the author has presumably taken stock of all those old oiled dirt roads, only a few of which can be considered at all as oil macadam.

It is true that at first there were no fixed specifications for work of this class. It was then in the experimental stage, and each engineer was doing his own experimenting at the expense of city, county, or State. In Los Angeles County alone probably $1 500 000 were practically wasted during this experimental stage, simply because the engineer then in charge refused to profit by the experience and advice of others, but would learn for himself. Other cases of the same kind have occurred, and these unfortunate conditions have done much to blacklist pavements of this type. At present engineers engaged in work of this class have adopted similar specifications and are obtaining general success.

The author states that the successful examples of pavements of this type have been either in localities where climatic conditions are such as to evaporate the more volatile parts of the oil, or where the application has been made in such a manner as to obtain the same results. Now, if success is obtained by a certain method in one place, would it not be good practice to adopt such a method in other localities? As a matter of fact, an asphaltic oil which will meet the requirements of the usual specifications as now adopted has practically no lubricating properties and very little volatile matter. The foundation stones are laid and rolled until a thorough mechanical locking of the particles takes place and it is as firm and solid as a water-bound macadam pavement; then the oil, at a high temperature, is sprayed on under pressure in such a manner that it is in a finely divided state and penetrates the interstices of the stone, acting primarily as a binder. Constructed in this manner, there can be no rolling or movement of the stones, as is pointed out by Mr. Hammatt. The wearing surface of finer aggregate is then laid on this foundation.

The patented form of Petrolithic pavement is by no means an oil macadam pavement. It is merely an earth road with sand and oil incorporated to a depth of 6 or 8 in., forming a thick rubbery mat, which is pushed and pulled by the traffic stresses until it is resolved into a series of humps and hollows. In a hot climate it remains soft and spongy, and soon becomes so wavy and covered with ruts that it is almost impassable. The Petrolithic Company's tamping roller, however, has come into very good use in compacting sub-grades and earth roads. The prongs, or sheep's feet, of this roller reach through

to the bottom of the sub-grade, and, starting there, compact it uniformly all the way to the surface, making a solid crust or arch to carry the weight of the finished pavement and its transmitted stresses. Mr. Hoar.

Probably the strongest argument against bituminous or oil-macadam pavements is the difficulty of obtaining good inspection, which must be had to secure satisfactory results. On the contrary, an argument put forth by the advocates of concrete roads is that, because of this lack of trustworthy inspection, concrete is the only type from which satisfactory and certain results can be obtained. In practice, however, this has proven to be far from the truth. The argument is that, no matter how little care has been taken in the preparation of the sub-grade, or how poorly the concrete has been mixed, it will become hard and form a good solid foundation, and will carry the traffic safely over the bad places in the sub-grade. Experience, however, has shown that, to secure satisfactory results with concrete roads, just as much attention must be given to the inspection as for any other type; for lack of the proper quantity of cement or poor and insufficient mixing is soon indicated by rapid disintegration.

The type of wearing surface which has met with the greatest success on roads having a concrete base consists of a $\frac{3}{8}$-in. coat of oil and crushed stone screenings ranging in size from $\frac{3}{4}$ to $\frac{1}{4}$ in. The oil is thus almost uniformly exposed to the action of the atmosphere, which causes it to "set", thus cementing the particles of the aggregate well together and to the base. As the coat is thin and uniform, it is easily applied, cheaply maintained, and permits of equal compression throughout the mass.

W. C. HAMMATT, M. AM. SOC. C. E. (by letter).—As was expected, the writer's condemnation of oiled macadam pavements brought out some contradiction. Although this type of pavement has lost many of its advocates, there still remain many who believe in its value as a pavement. The writer, however, maintains that only a small proportion of the total mileage of oiled macadam pavement which has been laid, has been successful, and he does not include the oiled dirt and gravel roads under this heading. He knows of no road in the central part of the State, which has been under varied traffic for two years, which has remained in good condition without an expenditure of at least 8 cents per sq. yd. for repairs. There are some, where traffic is restricted to pleasure vehicles, which have remained in good condition, and these are cited as examples by advocates of this class of pavement. Mr. Hammatt.

The value of oil as a road material lies in the formation of a surface skin by the volatilization of the lighter constituents. This skin is very durable, and as long as it remains intact, it protects the general body of the pavement. In the southern part of the State, where Mr. Hoar's observations have largely been made, the sandy

Mr. Hammatt.

nature of the soil and the hot, dry climate are such as to increase the thickness of the skin. Nevertheless, in examining the roads between Los Angeles and Pasadena, the writer has noted that those carrying the automobile traffic are the only ones which hold their shape.

To sum up, the justification for the adoption of a certain type of pavement can only be from its structural excellence or its economic value. One type will not be justifiable if another type will make a better appearance and keep in better condition at a smaller cost. The writer's experience has been that a protected water-bound macadam pavement will do this. This type may be made to fit all conditions by varying the thickness of the base and of the protective covering. A macadam pavement, 6 in. thick, with a skin protection of asphalt and screenings, will cost about 70 cents per sq. yd., and will require an annual expenditure of about 9 cents per sq. yd. for upkeep. Increasing the protective covering to 2 in. in thickness of asphaltic macadam increases the cost to about $1.10 per sq. yd., and the upkeep will be nil for from 10 to 15 years. Compare these costs, as well as the appearance and usefulness of the pavement, with oiled macadam under the best conditions, and the writer believes that there will be no justification for the latter.

A skin of oil and screenings has been applied to some of the concrete bases of the State highway for their protection. This has been quite successful, as pointed out by Mr. Hoar, for the reason that the oil does not penetrate the concrete, and the concrete, by absorbing heat, promptly carbonizes the oil and hardens the skin. Moreover, for so thin a coating, it is probable that oil is better than asphalt, as the coating will be more resilient and cause less impact on the concrete.

MEMOIRS OF DECEASED MEMBERS.

NOTE.—Memoirs will be reproduced in the volumes of *Transactions*. Any information which will amplify the records as here printed, or correct any errors, should be forwarded to the Secretary prior to the final publication.

EMIL GERBER, M. Am. Soc. C. E.*

DIED APRIL 16TH, 1914.

Emil Gerber was born in Reichenbach, Saxony, on January 31st, 1858, and died in Pittsburgh, Pa., on April 16th, 1914. His father, C. F. Gerber, was born in 1819 and died in 1899. He was a designer and manufacturer of textile fabrics, and introduced the use of power looms in his native town. His mother's maiden name was Christliebe Klotz, daughter of Carl Klotz. His ancestors for several hundred years were residents and prominent citizens of Reichenbach, Saxony. His father came to the United States in 1862 and settled in Webster, Mass., and in 1867 his mother came to Webster, bringing Emil and his two brothers, Herman and Carl.

He was educated in the common schools of Webster, Mass., and the Stevens High School at Claremont, N. H. In the fall of 1873 he entered the Worcester Polytechnic Institute, at Worcester, Mass., and was graduated as a civil engineer in the spring of 1876, being at that time only a little more than eighteen years of age. A classmate states that he was very much liked by all the students and professors. He was studious, a man of high character, and at that time gave promise to do good work. The President of the Institute writes: "Few students have done better in the Institute."

Mr. Gerber taught school for one year at Southbridge, Mass., and was employed as a bookkeeper in a corporation store connected with the woolen mills in Webster, Mass., until May 1st, 1879, when he was engaged as a Transitman on the Fremont, Elkhorn, and Missouri Valley Railroad. In May, 1880, he became Locating Engineer with the same railroad, and in 1881 was promoted to the position of Assistant to the Chief Engineer, Captain James Edward Ainsworth. On August 1st, 1881, he was appointed Assistant Engineer on the Blair Bridge over the Missouri River, near Blair, Nebr., built by the Sioux City and Pacific Railroad which later became a part of the Chicago and Northwestern Railway. The late George S. Morison, Past-President, Am. Soc. C. E., was Chief Engineer of this bridge. Toward the completion of this work, on November 1st, 1883, Mr. Gerber was made Resident Engineer.

In October, 1884, he returned to his former position with the Fremont, Elkhorn, and Missouri Valley Railroad, but still retained charge of the Blair Bridge and its extensive protection works.

* Memoir prepared by Otis E. Hovey and August Ziesing, Members, Am. Soc. C. E.

In November, 1885, he was appointed Assistant Chief Engineer of the same railroad, which position he held until he resigned on June 15th, 1887, to become Resident Engineer of the Sioux City Bridge over the Missouri River, of which Mr. Morison was also Chief Engineer. This bridge was completed at the end of 1888, and Mr. Gerber was then appointed Resident Engineer of the bridge over the St. Johns River at Jacksonville, Fla., which was being built by the Jacksonville, St. Augustine, and Halifax River Railroad, with Mr. Morison as Chief Engineer. A severe illness prevented Mr. Gerber from completing this bridge, and in May, 1889, Mr. Morison placed him in charge of his Chicago office, where he remained until the fall of 1897.

During this period, he was connected with all Mr. Morison's important works, among which may be mentioned the Cairo, Memphis, Burlington, Winona, Bellefontaine, Alton, and Leavenworth Bridges; the Chicago, Burlington, and Quincy entrance into St. Louis, and many less important works.

In 1897, Mr. Gerber resigned his position with Mr. Morison to become Chief Engineer of the Lassig Bridge and Iron Works, in Chicago, Ill. He held this position until the spring of 1900. When the American Bridge Company was formed, he was made Manager of the Lassig Plant. In July, 1901, he was promoted, becoming Assistant to the President of the American Bridge Company, in Philadelphia, Pa. Early in 1904, he went to Pittsburgh, in the same position, and in the fall of 1905 was made Operating Manager of the Pittsburgh Division in addition to his position as Assistant to the President. In 1911, he was relieved as Operating Manager and made General Manager of Erection, but still held the title of Assistant to the President. He held this position during the remainder of his life.

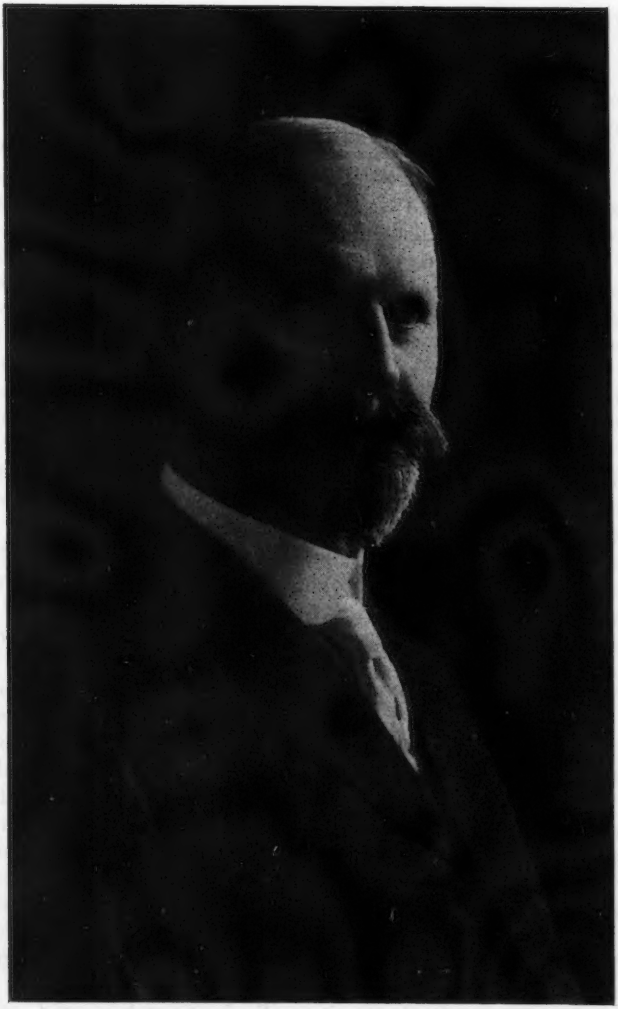
He was married on January 3d, 1882, at West Roxbury, Mass., to Caroline Herthel, daughter of F. J. Herthel, Sr., and is survived by his widow, a daughter, Mrs. Laura E. Olson, of Chicago, Ill., and a son, Emil Gerber, Jr., of Pittsburgh, Pa.

As is often the case with engineers fully and continuously engaged on important work, Mr. Gerber was not a frequent contributor to engineering literature, but whatever he wrote is strongly marked by his vigorous personality.

He was the author of a paper entitled "Painting of Iron Structures Exposed to Weather",* and also of one entitled "Some Commercial Features of Structural Engineering".† He had based a few lectures to young engineers on the latter paper, and his last brief illness and death prevented him from lecturing on the same subject before the American Bridge Engineering Club of New York. This paper is one which should be read by all engineers.

* *Transactions*, Am. Soc. C. E., Vol. XXXIII, p. 185.

† *Proceedings*, Eng. Soc. of Western Pennsylvania, Vol. XXIII, p. 125.



E. Gerber

It frequently happens that an engineer employed by individuals or corporations does not become so well and favorably known as he would have been had he been in practice under his own name. It is also common for an engineer associated with corporations to specialize along some narrow line of engineering work. Mr. Gerber was an exception in these respects. His early experience covered a very wide range of work, including railroads, difficult foundations, construction of bridges and other structures pertaining to railroads, and, at the time he took up his work as an engineer associated with a corporation, his experience was wide and his judgment well trained.

Those closely associated with him were impressed by the thorough manner in which he carried out any work on which he was engaged, his genial and helpful disposition, and his hearty and liberal endeavors to assist those around him in every way. He was a man who would ungrudgingly draw from his experience anything that would help his associates to grasp an engineering or business situation with which he was familiar.

He never did anything superficially. Any problem that was before him received his complete and earnest attention. Whenever he undertook an investigation or made a report, one could depend on his having gone into the matter thoroughly and having expressed his best opinion; and any facts contributed to the subject could be depended upon.

Mr. Gerber had a strong mentality and firm opinions on any subject to which he had given thought, but at the same time was always willing to discuss exhaustively the opinions of others, and when they were backed by facts and good reasoning was ready to modify his previous views in an eminently fair-minded manner.

A notable trait of his personality was his unusual ability in the establishment of cordial relations with his associates, and his interest in all that contributed to their welfare.

On account of his connection with a multitude of engineering works to which he contributed in more or less degree, and in which his strong common sense and clear thinking determined important decisions concerning designs and methods of construction, it is unfortunate that the Profession cannot point definitely to this or that work as purely his own. His monument is a more personal one. His strong, honest, thorough, and genial personality has impressed itself on all who knew him, and most of all on those who knew him intimately. Such characters are an inspiration to all members of the Profession.

Mr. Gerber was elected a Member of the American Society of Civil Engineers, on February 1st, 1888, and served as a Director from January, 1912, until the time of his death. He was also a member of the American Railway Engineering Association, the Western Society of Engineers (Past Treasurer), the Engineers' Society of Western Pennsylvania, the Chicago Engineers Club, and the Duquesne Club and the Junta Club, both of Pittsburgh.

HENRY FRANCIS LABELLE, M. Am. Soc. C. E.*

DIED DECEMBER 12TH, 1913.

Henry Francis Labelle was born in Montreal, Que., Canada, on January 31st, 1860. His father, Regis Labelle, was a lumber merchant, and was a native of Jirome, in the Province of Quebec. His mother, Lucille Marceau, was born at Lacolle, in the same Province.

After his graduation from St. Mary's College, Montreal, he entered the Montreal Polytechnic School, from which, in 1882, he received the degree of Civil Engineer.

Mr. Labelle's first employment was as Rodman and Draftsman for the Chicago, Burlington and Quincy Railroad. In August, 1883, he returned to Canada, and, after about a year in the Dominion Lands Office, entered the office of the Chief Architect, Department of Public Works, Canada, where he was employed until 1890, during the last two years as Assistant Superintendent of Public Buildings. From 1890 to 1895, he was employed as Assistant Engineer or Engineer in Charge of the design and construction of numerous municipal water supply systems in New York, Pennsylvania, and Maryland.

By disposition and training Mr. Labelle was peculiarly fitted for the varied and interesting problems of hydraulic and hydro-electric engineering design, and after once entering this branch of the Profession, he did not leave it.

He was for several years in the employ of the East Jersey Water Company, the latter part of the time as First Assistant Engineer in charge of the Montclair office and of construction work amounting to approximately $1 000 000. In 1895, and again in 1900, he was employed by the Susquehanna Power and Paper Company, on surveys and designs for a 35 000-h.p. development on the lower Susquehanna River, and in 1902 by other parties on investigations and studies of power possibilities on the same river at Turkey Hill.

In 1901, he was appointed Designing Engineer on a new water supply for Santiago, Cuba, for the Military Government. In the latter part of 1902, he returned to Cuba where, for some time, he was engaged by Havana interests as Engineer to report on or design water supply and electric power and light systems.

In 1904 Mr. Labelle accepted employment under the Philippine Government, first as Engineer in Charge of all irrigation work in the Islands, under the Director of Public Works, and later as Principal Assistant Engineer on the construction of the new Manila Water-Works. While in charge of the irrigation works, he prepared a system of irrigation laws for the Islands.

In 1907, on account of threatened lung trouble, he was advised by his physicians to leave the Philippines. He returned to the United

* Memoir prepared by John T. Whistler, M. Am. Soc. C. E.

States, and located in Silver City, N. Mex., where he remained until 1911, when heart trouble compelled him to change from the high altitude to a lower one, and he moved to Albuquerque, N. Mex., where he remained until his death.

It was typical of his character that he wrote of his heart trouble in 1911, "I now have the choice of two ways to die. I can either remain in Silver City and die of heart trouble, or I can go to Albuquerque and die of lung trouble."

After several months of correspondence and inquiry as to his experience and qualifications, he was notified, on November 5th, 1911, of his employment by the Argentine Government to act as Adviser in the development of an Irrigation Bureau. It was just at this time that his complication of heart trouble had developed, and, much to his regret, he was compelled to decline the office.

In 1908, he was married to Miss Emily Rose Woodford, of London, England, who for several years had been a resident of Philadelphia, Pa., and who survives him.

Mr. Labelle was the author of several discussions published in the *Transactions,* and had also contributed to various current technical journals. Though of foreign birth, he took out naturalization papers and became a citizen of the United States in January, 1904.

Altogether, Mr. Labelle was one of the sweetest and most noble characters with whom it was one's privilege to associate. He never complained, rarely spoke ill of any one, and then only with that calm judgment which guided his whole career. He never was known to do any one the slightest injustice. Simply to have known him was a privilege, to have known him intimately was an inspiration.

Mr. Labelle was elected a Member of the American Society of Civil Engineers on April 6th, 1898.

FRANK PARSONS LANT, M. Am. Soc. C. E.*

DIED JUNE 30TH, 1914.

Frank Parsons Lant was born at Nassau, N. Y., on May 24th, 1858, and was of Colonial Dutch descent.

His business career, which included many important positions, was begun on September 26th, 1881, when he was employed as Axeman, and, subsequently, as Rodman and Assistant Engineer on the location and construction of the West Shore Railway, holding the latter position until March 1st, 1884.

From June 1st, 1884, to December 31st, 1886, Mr. Lant was City Engineer and Surveyor of Hudson, N. Y., designing and constructing

* Extract from memoir prepared by Gerald E. Hart, Esq., of New York City and Jacksonville, Fla., supplemented by information on file at the Society House.

sewers, highways, etc. He was also engaged in the private practice of surveying and engineering during that time.

During 1887, and until March 1st, 1888, he was employed on the location of a branch line for the Erie Railway, in Pennsylvania, and also made the surveys and had charge of the construction of the foundations for the Myrtle Avenue Elevated Railroad, in Brooklyn, N. Y. During this period he made the preliminary and location surveys for the New York and Massachusetts Railroad, from Ancram Lead Mines, N. Y., to near Westfield, Mass.

From March to November, 1888, he served as Division Engineer on the preliminary and location work for a line over the Blue Ridge Mountains, north of Marion, N. C., for the Charleston, Cincinnati and Chicago Railway, and from November, 1888, to March, 1889, he was engaged on a revision of the location of the New York and Massachusetts Railroad from Ancram Lead Mines, N. Y., to Chicopee Falls, Mass. In April, 1889, he was placed in charge of the reballasting of 60 or 70 miles of roadbed for the Rome, Watertown and Ogdensburg Railroad.

In November, 1889, Mr. Lant went to Jamaica, West Indies, where he remained until July, 1891, making location surveys for the West India Improvement Company.

From August, 1891, to February, 1896, he was engaged in the private practice of engineering and surveying, during which time he made the plans for the disposal of ashes in the filling in around Riker's Island, a survey for a railway proposition on Long Island, etc., etc.

In connection with the public works of New York City, Mr. Lant served the City Government, as follows: From February, 1896, to October, 1897, he was Engineer Inspector in the Department of Public Works; from October, 1897, to July, 1898, Engineer of Grades (Commissioners' Engineer) on the electrification of the Second Avenue Railroad; from August, 1898, to February, 1902, Transitman and Computer in the Topographical Bureau of the Board of Public Improvements; and from February, 1902, to March, 1907, Transitman and Computer in the office of the Engineer of Street Openings.

In March, 1907, he was appointed Manager (which title also included that of Chief Engineer and Surveyor) of the Lawyers' Engineering and Surveying Company, of New York City, which position he held at the time of his sudden death.

Mr. Lant was married on November 11th, 1891, to Stella, daughter of the late Jacob L. Seixas, who, with his father and mother, survives him.

He was an ardent student in his chosen profession, to which he did honor. His capabilities were such that his services and advice were frequently sought in cases of special importance. He possessed

in a high degree the power to command loyal service from his subordinates, as well as the confidence and respect of all who knew him. His genial manner and kindly nature will long be remembered by many who, in his death, experience a sense of personal loss.

Mr. Lant was elected a Junior of the American Society of Civil Engineers on October 3d, 1888, and a Member on February 1st, 1910.

ULYSSES STANISLAUS LUTZ, M. Am. Soc. C. E.*

DIED DECEMBER 8TH, 1913.

Ulysses Stanislaus Lutz, the son of Ignatius and Rose Jacwuin Lutz, was born in Philadelphia, Pa., on May 25th, 1853. He received his earlier education at Roth's Military Academy, and was graduated in 1873 at the head of his class from the Philadelphia Polytechnic Institute, with the degree of Civil Engineer.

In 1873 he was engaged as Rodman on the South West Pennsylvania and the Lewisburg, Centre, and Spruce Creek Railroads. In 1874 he served as Leveler on the Tyrone and Clearfield and New River Railroads; in 1875 as Rodman on the Pennsylvania Railroad; in 1876, as Transitman on retracing the old Portage Railroad; from 1877 to 1879, as Assistant Supervisor, Maintenance of Way, on the Pittsburgh and Philadelphia Division, of the Pennsylvania Railroad; in 1880, as Supervisor, Maintenance of Way, on the Shenandoah Valley Railroad; from 1881 to 1885, as Assistant Engineer on Surveys for the South Penn Railroad, for two years, and for two years as Resident Engineer in charge of Subdivision B, Division 5, of the South Penn Railroad, in Somerset County; in 1886, as Principal Assistant Engineer on the location and construction of the Bloomsburg and Sullivan Railroad; in 1887, as Principal Assistant Engineer on the location of the Baltimore and Drum Point Railroad; in 1888 as Construction Engineer of the 25th Ward Gas Works, in Philadelphia, Pa.; in 1889, as Division Engineer on the location and construction of the Cumberland Valley Extension of the Louisville and Nashville Railroad.

For a time Mr. Lutz followed private practice in Virginia and North Carolina, and, in 1892, became Constructing Engineer for the Pennsylvania Iron Works. In 1893 and 1894, he was Chief Engineer on the location and construction of the South Jersey Railroad, and thereafter was engaged on the construction of electric railroads in and around Baltimore, Md., having been, in 1895 and 1896, Manager of Construction for the Baltimore and Catonsville Railroad.

* Memoir prepared by Charles W. Staniford and S. L. F. Deyo, Members, Am. Soc. C. E., and John H. Frazee, Assoc. M. Am. Soc. C. E.

In 1897, he entered the service of the City of New York in the Department of Public Works, being first engaged on the Park Avenue Change of Grade Improvement from 56th to 96th Streets in Manhattan.

Mr. Lutz left the City's service to go with his former Chief, the late William F. Shunk, as Chief Assistant Engineer on the location and construction of the Quito and Guayaquil Railroad, in Venezuela, and again to go with the Iowa and Minnesota Railroad, as Assistant Engineer on Construction.

In 1905, he entered the Department of Finance of the City of New York, as an Assistant Engineer, and held that position until his death, which occurred on December 8th, 1913, after an illness of three weeks.

Mr. Lutz's practical knowledge acquired through a long and varied engineering experience was of great service to the City. He was an indefatigable and conscientious worker, and those with whom he was associated were impressed with his sense of loyalty to the City and to his friends.

Mr. Lutz was elected a Member of the American Society of Civil Engineers on March 5th, 1912. He was also a member of the Masonic Fraternity.

LEON LINCOLN GAY, Assoc. M. Am. Soc. C. E.*

DIED MAY 6TH, 1914.

Leon Lincoln Gay, the only son of Carlos E. and Calista Gay, was born at Barton Landing, Vt., on May 30th, 1879. He obtained his education at the public schools, and was a graduate of St. Johnsbury Academy. He then entered the Sheffield Scientific School, of Yale University, from which he was graduated in 1901, with the degree of Ph.B. While at Yale, he was a member of the Track Team and made some good records as a long-distance runner.

In the fall of 1901, Mr. Gay went to Idaho to become Assistant Engineer in charge of the construction of a small power plant at Horseshoe Bend, under A. J. Wiley, M. Am. Soc. C. E., Consulting Engineer. On the completion of this plant, he entered the United States Reclamation Service as Engineering Aid, and was engaged on the preliminary work for the Minidoka Project, in Idaho, during the greater part of 1903 and 1904. During the construction of the Minidoka Dam, on Snake River, he was Assistant Engineer on that work. On its completion, he was assigned to take charge of the building of the original Jackson Lake Dam, near Yellowstone Park, in Wyoming, and made an enviable record in completing this temporary

*Memoir prepared by C. W. Joslyn, Esq., and F. C. Horn, M. Am. Soc. C. E.

dam at a remarkably low cost. Later, he was Principal Assistant Engineer in charge of the construction of the Boise River Dam, of the Reclamation Service, near Boise, Idaho.

In 1908, Mr. Gay resigned from the Reclamation Service to accept a position as Engineer for a large irrigation enterprise in the Sacramento Valley, California. The following year he was attacked with tuberculosis, and the last five years of his life was a continuous fight with this dread disease to which he finally succumbed while undergoing an operation in Montreal, Que., Canada.

Mr. Gay was known by the large number of engineers of his acquaintance in the West to be a man of high moral character and absolute integrity. He was considered one of the most capable young engineers in the line of irrigation in the United States, and previous to his unfortunate illness he had executed some important and successful work. His misfortune and death are peculiarly sad. He was a typical New Englander, and among his near friends, his humor and originality gained for him the affectionate nickname of "the Yank".

He is survived by his father and stepmother, of Orleans, Vt., as well as by his two sisters, Mrs. Wallace C. Gilpin, of Barton, Vt., and Mrs. Fred E. Parker, of Falls Church, Va.

Mr. Gay was elected a Junior of the American Society of Civil Engineers on December 5th, 1905, and an Associate Member on October 2d, 1907.

PHILIP MORRIS PRITCHARD, Assoc. M. Am. Soc. C. E.*

DIED JULY 8TH, 1914.

Philip Morris Pritchard was born on April 29th, 1872, at Rock Ferry, near Birkenhead, England. He was educated in London, where his father was in business as a tea importer and merchant. At an early age the boy showed a strong liking for Engineering, and after his graduation from Kings College, London, in 1891, he was sent to Newcastle-on-Tyne to serve an apprenticeship of four years with the firm of R. and W. Hawthorn, Leslie and Company, Limited, Locomotive and Marine Engineers and Shipbuilders, where he received a thorough practical workshop training. During three years of his apprenticeship, he attended the Engineering Course at Durham College of Science, at Newcastle, and, on his graduation, was awarded an Associateship in Science.

In June, 1895, Mr. Pritchard was engaged as Draftsman and Assistant Engineer at the Tennant-on-Tyne Works of the United

* Memoir prepared by the Secretary from information supplied by the United Alkali Company, Limited, Widnes, England, supplemented by information on file at the Society House.

Alkali Company, Limited. In January, 1896, the Company organized its Engineering Department at Widnes, England, and he was brought from the Tennant Works to occupy an important and responsible position on the engineering staff at the latter place. This promotion eventually led to his appointment as Chief Engineer of the Company, a position which he held for about 12 years and at the time of his death on July 8th, 1914.

While in charge of the Engineering Department of the United Alkali Company, Limited, Mr. Pritchard was engaged in the design and erection of much new plant in the English and American works of the Company and did valuable work in its Spanish mines.

All through his career, Mr. Pritchard showed brilliant ability as an Engineer, and his death is a great loss to the Company as he was greatly esteemed both by the Directors and his colleagues.

He was a Member of the Institute of Mechanical Engineers and of the Society of Chemical Industry. He was also an Associate Member of the Institution of Civil Engineers.

Mr. Pritchard was elected an Associate Member of the American Society of Civil Engineers, on June 6th, 1900.

FUNDAMENTAL PRINCIPLES OF PUBLIC UTILITY VALUATION.

By John W. Alvord, M. Am. Soc. C. E.

To be Presented November 18th, 1914.

Synopsis.

This paper is undertaken as a consequence of the voluminous discussion of the writer's prior paper: "The Depreciation of Public Utility Properties as Affecting Their Valuation and Fair Return,"* presented December 17th, 1913. That discussion, though it showed the greatly increased interest which valuation matters are now receiving, also seemed to show that many engineers lack a clear perception of the fundamental principles involved in valuation work, presumably because such principles are to be found only in the law and the interpretation of the law by the Courts.

This paper shows that the science of valuation calls for a knowledge in three professions or callings: the law, engineering, and economics, and that, fundamentally, it is the law, and its interpretation by the higher Courts, which controls.

The fundamental definitions of value and property are given, and the constitutional conception of what it is that is to be valued

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

* *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 788.

is shown, with citations from leading cases passed on by the Supreme Court.

The point is made that the law determines that it is a "property" rather than an actual past investment that is to be valued, and that the value must be found as of to-day.

The fact that we are to value a property as of to-day indicates why the reproduction method obtains its importance, but it is made clear that reproduction is only a cost method, that cost is not value, and that the Courts have indicated that all lines of material evidence should be examined.

An outline is given of the various lines of evidence that should be summed up, including evidence that cannot be expressed well in figures.

Reproduction is thus examined only as a line of cost evidence, and its conceptual requirements are discussed, illustrated, and summarized. Past cost is also discussed as a line of cost evidence, and its deficiencies in throwing light on value now are pointed out; misuse of cost evidence methods is explained, other lines of evidence not readily reduced to cost figures are described, and, finally, the importance of reasoning from cost lines of evidence—as well as other evidence—to value is emphasized and illustrated.

To summarize, it has been attempted by this paper to show:

First.—That it is quite idle for engineers, appraisers, utility commissions, and others to argue about the detailed methods of valuation unless they have a fundamental and uniform conception of what "value" and "property" are, in the first instance, and what the reasoning of the Courts has been on these subjects.

Second.—That, fundamentally, the art of valuation must rest in the law and the interpretation of the law by the Courts, and especially the Supreme Court of the United States, this being the final authority in valuation matters.

Third.—That the Supreme Court has repeatedly ruled that it is the value of the property used for the public purpose that must be considered, and it is the value of that property now.

Fourth.—That most of the utility commissions and many estimators who have been following their rulings are at variance with the opinions and decisions of the Courts, in that they are insisting on retracing an investment rather than valuing a "property."

Fifth.—That the reproduction method is in most cases a most useful line of inquiry in arriving at a conclusion as to what the value of a property may be at the present time, but that it is not the only line of evidence to be considered.

Sixth.—That reproduction is a cost method and does not of itself determine value. It is only one of the means; not an end.

That the reproduction must be complete in itself, including going costs, before it can be properly used to reason from.

Seventh.—That when all lines of evidence are properly before us, we must reason as to what bearing on value each one of them may have.

A list of important legal decisions is appended to the paper.

Introductory.

The problem of valuing the property of public utilities is a difficult one, largely on account of the fact that there is required a knowledge of certain fundamental principles of law, of engineering, and of economics or finance. No one of these professions has within itself all the training and information which must be brought to bear on the problem, in order to make an equitable valuation. Experience and information from all of them must be utilized to ensure sound conclusions.

The Courts are somewhat prone to criticize expert witnesses because they do not agree, forgetting often that the fundamental data are indeterminate; financiers and economists are impatient because judges and lawyers do not appreciate the natural laws of business and the reasoning of sound economics; and, finally the engineering specialist becomes irritated with the Courts because his views on such subjects as "property rights," "franchises," "past cost," and "present value" are not deferentially treated, little realizing that he is here speculating entirely within the domain of the legal profession, and is often guilty of attempting to make law, where much more competent and well-trained minds have long been at work in the endeavor to produce sound reasoning. The engineer is especially impatient because the economist sees no practical difficulties or uncertainties in construction, and both the economistic and legal type of mind are too prone to regard the engineer as primarily a mathematician, who

should produce exact results even from inexact data, little realizing that engineering work is often more judicial than mathematical in its ordinary application and practice.

It must be apparent that it is quite useless to endeavor to discuss intelligently the details of valuation work unless somewhere the underlying principles, both as regards engineering and the law and economics, are co-ordinated, and their relative value to the problem in hand is fully appreciated. It is the purpose of this paper to attempt this somewhat ambitious task.

Definition of Terms as Used in this Paper.

In the present state of confusion as to valuation nomenclature, it is desirable to define the meaning of the more important terms used in this paper, as follows:

Property.—That which is owned; that which belongs exclusively to an individual; that to which a person has a legal title (whether in his possession or not); the exclusive right of possession, including all the rights which accompany ownership and is its incident.

Value.—The sum of the desirable qualities which render a thing useful and sought, measured in money; a measure of the relation of two services growing out of the adjustment of mutual needs.

Market Value.—The adjustment of two services, *i. e.,* as between a willing seller and a willing buyer under open conditions of competition.

Cost.—The actual outlay of money, or its equivalent, for a property, structure, or machine.

Past Cost.—The amount of money, or its equivalent, actually expended in the past in creating and building up a property.

Investment.—The amount of capital, or its equivalent, actually expended for a property in the past.

Reproduction Cost.—(Used in this paper generally as a short term for reproduction less depreciation.) An estimate of the cost of recreating a property at the present time under conditions that are humanly possible and practical.

Depreciation.—The lessened value of any property, structure, or machine, due either to its wear, loss of usefulness, growing lack of adaptation, or approaching abandonment.

Appreciation.—The increase in worth of a property, structure, or machine, due to its increasing use, strategic location, the increasing need for its service, or other like influences.

Amortization.—The repayment of an original investment or debt by means of sinking funds, or other moneys set aside from time to time in expectancy of obsolescence.

Public Utility.—A business supplying a public need, and based on a public grant.

Monopoly.—A business having exclusive power of dealing in a service, and thus conducted without competition.

Franchise.—A grant by the public of the necessary rights to do a specific business.

Other definitions might be included, pertaining more to the details of appraisal work, but as it is the intention here to limit the discussion as far as possible to fundamentals, it is believed that the foregoing will suffice.

Law—The Foundation.

The fundamental principles of the science of valuation must rest primarily on the law, and to an adequate knowledge of the law must be added a knowledge of the interpretation of the law by the Courts in their decisions and opinions. Courts are not free to reach conclusions on broad general principles; their function is, not to say what the law ought to be, but simply to interpret it as it is. They, as well as economists and engineers, must accept fundamental law as it stands; their duty is to tell us what this fundamental law means.

The function of the lawyer, therefore, in utility valuations, is to call the attention of engineers, economists, and appraisers to the law and to the interpretation of the law by the Courts, and to assist in its application to the facts, and this is a fundamental and important matter. What is to be determined, and the material factors to be taken into account in its determination, are questions of law, exclusively. It is in this connection that the utility commissions, the economist, and the engineer usually make their most serious mistakes. Disregarding the legal basis on which all valuation work must rest, their attempts to decide difficult and important legal questions on the strength of their own general judgment, knowledge, or practice, alone, without any inquiry into the law governing such questions,

naturally adds seriously to the confusion and difficulties surrounding an already complex problem.

The final authority for the interpretation of the law, which is the foundation on which the work of public utility valuation in this country must be built, is the Supreme Court of the United States. Its decisions, until modified, must be regarded as authoritative and final. Next in importance, in interpreting the law, come the decisions and opinions of the higher State Courts, which have been studying and applying the law to questions of this kind for the last fifteen or twenty years, producing an historically connected body of reasoning which no serious student of valuation work can afford to remain in ignorance of or neglect. The utility commissions are all subject to review by the higher Courts, and are, therefore, in effect specialized lower Courts or legalized appraisal boards with enlarged and extended powers.

The interpretation of the law by the Courts has in it little of permanent value, unless it expounds the fundamental law along the lines of sound reasoning and justice. With great responsibilities resting on them, Courts naturally proceed cautiously, rarely stepping outside of the necessities of the particular case in which they have to produce a finding, and yet progressing step by step, so that, as new applications of old principles are needed, there is slowly built up a rational line of reasoning which is of the greatest fundamental value. It must be admitted that Courts ofttimes get confused and bewildered when unexpectedly called on to determine purely economic or technical questions. It is not unjust to say that in some cases judges are unfitted by prior training and so handicapped by lack of time as to prevent them from mastering the economic or technical problem before them. Under such circumstances, they sometimes make technical mistakes in their decisions, which are unfortunate because they delay progress. When a Court is bewildered by contradictory expert testimony, it occasionally reveals its embarrassment by criticizing the experts. Courts should realize that truth often lies in a twilight zone, and that this twilight zone may be much narrowed down by the services of good, specialized, and competent witnesses in their calling, and Courts ought to be so skilled in human nature as to be able to disassociate the able and mature from the immature and pretentious witness on specialized subjects.

Taking it all in all, however, Courts are conservative, and their reasoning is usually sound. They are cautious, also, and venture into new and uncharted seas slowly, sounding by sounding. The exceptions prove the rule, and the engineer, in studying their decisions, will not run amiss if he takes the general results of their interpretation of the law as a safe guide. Courts and appraisers are both bound by the law. Whether it is such law as we would make ourselves is outside of the question; the law as we find it must govern us.

The Engineer in Valuation Work.

Although valuation work is based on law, and should adapt itself to the decisions of the Courts, yet the larger portion of the actual work of the valuer will be done in the capacity of the engineer, because almost all utility properties are essentially engineering projects, in which engineering experience, skill, and activity are predominant. The engineer, therefore, building soundly on the fundamental requirements of the law, may proceed to matters more properly within his own jurisdiction, where his accumulated practical experience with the laws of Nature and the constructive works of man will play the larger part.

Economics.

To the resources of the law and to the practical experience of the engineer must be added a third realm of information, which is, in many ways, a distinct domain by itself: that of finance or economics. Too often neither the engineering nor the legal mind is well trained in the great practical world of business, nor realizes the fluctuating value of money, nor is skilled in that class of problems which relates to the conservation of wealth, its limitations, use, and abuse. It is quite true that the more mature engineer should, and often does, know in a general way a good deal about finance, particularly if he has been much occupied with the broader aspects of engineering; that is to say, in those relationships where projects are financed and placed on a sound business basis. The great majority of engineers, however, do not come at all in contact with the preliminary operations under which projects are financed, and are often not well informed, and sometimes regrettably opinionated on matters of this kind. The nature and the duties of members of the legal profession are such that they are probably more often called into consultation as to the larger financial

questions than the great body of engineers, but even the practice of law does not always bring about a practical working knowledge of the ordinary rules that govern and guide the financier.

Utility Experts.

Taking advantage of the fact that there are many fields of knowledge in utility valuation which must be mastered in part, there has sprung into existence of late the term "public utility expert," obviously growing out of the desire to describe a composite calling, able to offer all the knowledge which must be possessed by a public utility valuer in all classes of valuation matters. There can be little question as to the futility of such enterprise.

It is impossible for any man to be a thoroughly competent expert in all phases of even one profession, and the work of valuation requires the co-operation of experts from several professions, and, as well, engineering specialists from each type of utilities to be valued. If there ever was a place where a "Jack of all Trades" is worse than useless, it is in valuation matters. The Courts and commissions are already overburdened by the necessity of listening to ambitious inexperience and voluble plausibility posing as experts, and the all-round expert, who can value anything under the light of the sun, should not be tolerated. If we are to have progress and justice, we should emphasize the importance of having co-operative effort from the most mature class of specialists in every line of specialized endeavor.

Value.

Turning now to some of the fundamental things which the law outlines as a foundation for all valuation processes, we may properly, first of all, inquire what value is. It would appear that this is a very simple question, but it is astonishing how few engineers, for instance, make any distinction at all between "value" and "cost." To grasp clearly the distinction between value and cost is one of the first fundamental principles which an engineering appraiser must learn. Very little reflection is needed to convince one that a thing may be worth much more than it cost, or it may be worth much less. It may even be worth more than it would cost new at the present time, or worth much less. This fundamental conception the legal profession and the economists almost always have well in mind, but it is often a

new thought to the engineer. This is because the engineer is largely dealing with new construction, in which cost most often approximates value.

Let us see what the Courts have said about so simple a thing as value:

VALUE DEFINED.

"Value is the relation of two services. The idea of value entered into the world for the first time when a man said to his brother, 'Do this for me, and I will do that for you.' They had come to an agreement. Then we could say the two services were worth each other." (State *v.* Yates, 10 Ohio, Dec. 150, 158; 19 Wkly. Law Bul., 150.)

"The word 'value' means the exchange power which one commodity or service has in relation to another." (State *v.* Yates, 10 Ohio, Dec. 150, 158; 19 Wkly. Law Bul., 150—citing Walker, "Science of Wealth.")

"The word 'value', in its commonly received signification, means the sum of money a thing will produce to the seller when sold. We are aware that this is not abstractly the true measure of value. The quantity of labor and capital necessary to produce a given article, or, in other words, the actual cost of its production, is the true criterion of its worth. For instance, if a manufacturer be asked the value of a yard of cloth, his opinion of value will be determined by his calculation of the expense of producing a yard of cloth of similar quality. If we ask a retail dealer the value of a yard of cloth, his opinion of its value will be determined by the quantity of money such an article will produce in the market. It is apparent that the marketable value may be affected by a multitude of circumstances which will not in their results extend to the cost of production.

"Value is in its nature so vague and indefinite that no human scrutiny can seize all its constituent parts, and, therefore, opinions of value are admissible in evidence from the necessity of the case." (Town of Rochester *v.* Town of Chester, 3 N. H., 349, 358.)

"The term 'value' in a constitutional provision that property shall be taxed according to value, means the worth of the property as compared with the money of the country—the standard by which all values are regulated." (City of Chattanooga *v.* Nashville, C. and St. L. R. Co., 75 Tenn. (7 Lea), 561, 569.)

"As market value. Bouvier, in his definition of value says: 'This term has two different meanings. It sometimes expresses the utility of an object, and sometimes the power of purchasing other articles with it. The first may be called the "value in use", and the latter the

"value in exchange." Webster recognizes a difference between extrinsic and exchangeable value. But in condemnation proceedings "value" will be held to mean market value.'" (Little Rock Junction Ry. *v.* Woodruff, 5 S. W., 792, 795; 49 Ark., 381; 4 Am. St. Rep., 51.)

"When applied to property, and no qualification is expressed or implied, 'value' means the price which the property could command in the market." (*In re* McGhee's Estate, 74 N. W., 695, 697; 105 Iowa, 9.)

"The word 'value', as defined by Bouvier, has two different meanings. It sometimes expresses the utility of an object, and sometimes the power of purchasing goods with it. The first may be called the 'value in use,' the latter, the 'value in exchange.' For the purpose of the law of eminent domain, the term 'value' has reference to the value in exchange, or market value. There are some cases which seem to hold that the value in use to an owner is to be taken if it exceeds the market value, but it will generally be found, on careful examination, that such cases either refer to the damages accruing to the owner from the taking, and not to the value of the property itself, or they overlook the distinction between the two things. The consensus of the best-considered cases is that for the purpose in hand the value to be taken is the market value." (San Diego Land and Town Co. *v.* Neale, 20 Pac., 372, 374; 78 Cal., 63; 3 L. R. A., 83.)

"The primary meaning of 'value' is worth; and this worth is made up of the useful or estimable qualities of the thing. Ordinarily, when an article of sale is in the market, and has a market value, there is no difference between its value and the market price, and the law adopts the latter as the proper evidence of value. This is not, however, because 'value' and 'price' are really convertible terms, but only because they are ordinarily so in a fair market." (Kountz *v.* Kirkpatrick, 72 Pa. (22 P. F. Smith), 376, 386; 13 Am. Rep., 687.)

"Value of Railroad. The value of a railroad track at any given time is not the original cost nor its ultimate cost after years of expenditure in repairs and improvements. On the other hand, its value cannot be determined by ascertaining the value of the land included in the roadway, assessed at the market price of adjacent lands, and adding the value of the cross-ties, rails, and spikes. The value of land depends largely upon the use to which it can be put, and the character of improvements upon it. The assessable value for taxation of a railroad track can only be determined by looking at the elements on which the financial condition of the company depends;—its traffic as evidenced by the rolling stock and gross earnings in connection with its capital stock." (Pittsburg, C. C. and St. L. Ry. Co. *v.* Backus, 14 Sup. Ct., 1114, 1118; 154 U. S., 421; 38 L. Ed., 1031.)

"The value of a railroad for purposes of taxation is not the mere value of its right of way, roadbed, its structure, its depot ground and structures thereon, considered by themselves, but the value of all these as an operating going concern; this value being in general determinable by the profits which result from its operation." (State *v.* Austin and N. W. R. Co., 62 S. W., 1050; 94 Tex., 530.)

It must be fully realized that, in public utility valuation, we are endeavoring to ascertain the fair value as between the public, on the one hand, with its needs for the service, and the owners of the property which has been devoted to the public use, and is practically incapable of extricating itself from that service, and, therefore, peculiarly dependent on just and fair treatment for its conservation.

Property.

Another of the fundamental concepts which should be well established in the mind of utility commissions and engineers is the meaning of the word "property." Here, again, it seems strange that any considerable difference of opinion should arise about a definition which has been so long a subject of inquiry as that of the word "property," and yet lack of a clear idea as to what is being appraised in a public utility is mainly responsible to-day for the wide divergence of views as to how to proceed and what to value.

One might well ask how it is possible to accomplish anything without preliminary agreement as to so fundamental a proposition. It must be conceded that it is fundamental, in valuation work, to know what it is we are to value, yet engineers and appraisers generally will pass out opinions as to the value of plants without any intelligent inquiry as to the fundamental conception of what they are valuing. This is where the law and the Courts lay a foundation that ought to be clearly in mind before one tries to discuss details or proceed to estimate.

There arise, from the prevailing fundamental misconceptions, two opposing schools of thought, born on opposite sides at interest, which, being radically at variance with each other, can, of course, find no common ground for agreement in detailed methods.

On one side is ranged a school of thought, consisting, for the most part, of the majority of those advocates of municipal ownership and operation who have first approached the subject largely from that side of the question. This school of thought, as well as

certain of the more recently formed utility commissions and their staffs, who have been influenced by such arguments, conceive that the utility should be examined largely from the standpoint of the actual cost, or treated as a past investment, and that it can be considered to have value only in so far as actual cash or money has been put into the plant and property. The common viewpoint of this class of appraisers is that this past cost should be stripped of all accretions and increments of growth that are not represented at some time or other by actual expenditures. Certain extremists of this class of thinkers would even strip the actual "past investment" of its appreciation in the value of land and other like appreciations, while confining value to the actual past cash cost. They would further deduct from it any depreciation that might be found to have accrued.

On the other hand, as an opposing school of thought, there has developed a class of valuers who hold that the plant and business of a utility company together constitute a "property", which may have accretions in value outside of actual cash investment, and that such property may appreciate through such accretions, just as it may depreciate through age, lack of adaptability, or other causes.

Now this is a very fundamental and important difference of opinion, and needs intelligent and fair-minded investigation before we are at all competent to enter into detailed questions of valuation. Are we to find the actual dollars that have been invested in a plant and business, or are we to find the value of the resulting "property"? What does it profit us to discuss details when this serious and fundamental difference exists? The two schools of thought that have approached this subject of valuation differ so widely on this question that it is safe to say that much more than one-half of all our time in Courts and before commissions is taken up with testimony and argument directed to the one or the other of these two theories. Most of the recent literature on the subject of valuation work bears evidence of a fatal disagreement on this one fundamental point.

Curiously enough, this important question is emphatically settled by the highest authority we have, or can hope to have: the Constitution of our country as interpreted by the Supreme Court of the United States.

Property is a well-defined word in the meaning of the law, and the Fourteenth Amendment to the Constitution of the United States

is fundamentally the authority under which the Courts proceed in the determination of fair value of property for use in the fixing of rates or the ascertainment of value for condemnation or sale. It reads, in part, as follows:

"Nor shall any State deprive any person of life, liberty, or property without due process of law."

The provision of the Fifth Amendment to the Constitution, controlling condemnation cases by the United States, reads as follows:

"Nor shall private property be taken for public use without just compensation."

In the Constitutions of the States are similar provisions in which the word "property" is used. The significant thing is, that whether we look to the Fourteenth or to the Fifth Amendment, or to the State Constitutions, what shall not be taken is "property." The Fifth Amendment prohibits the United States from taking property without compensation. The Fourteenth Amendment prohibits any State from taking property without due process of law.

Nor has there been left undecided the question, which property devoted to the public use shall be treated differently in respect to its ownership and right of protection from other private property, as will be shown by later quotations. What is here to be emphasized is that the fundamental law of our land does not use the terms "investment", or "cash cost", or "past cost", or "actual expenditure", or any one of the numberless approaches to actual cash investment that would be used if a property were not precisely meant, with all that the term involves.

However, it is now proper to inquire further: What is property? Let us look for a moment at some of the more common legal definitions.

Property Defined.

"The sole and despotic dominion which one man claims and exercises over the external things of the world in total exclusion of the right of any other individual in the universe." (2 Bla. Com., 2.) "The right to possess, use, enjoy, and dispose of a thing (56 N. Y., 268) which is in itself valuable (4 McLean, 603). The right or interest which one has in lands or chattels. (6 Binn., 94; 4 Pet., 511.) The free use and enjoyment by a person of all his acquisition without any control or diminution, save only by the law of the land. (2 Ark., 291; 61 Hun, 571.) The right of a person over a thing (*in rem*) indefinite in point of user." (Austin's Lectures.)

"Webster defines 'property' to be the exclusive right of possessing, enjoying, and disposing of a thing; ownership; an estate, whether in lands, goods or money." (Spring Valley Water-works *v.* Schottler, 62 Cal., 69, 72, 84. See also Banning *v.* Sibley, 3 Minn., 389, 404 (Gil., 282); McKeon *v.* Bisby, 9 Cal., 137, 142; 70 Am. Dec., 642.)

"The term 'property', as used in the Constitution, is not confined to tangible objects which can be passed from hand to hand, but includes those rights of possession, disposal, management, and of contracting with reference thereto, which render property useful, valuable, and a source of happiness, the right to the pursuit of which is preserved." (State *v.* Kreutzberg, 90 N. W., 1098, 1100; 114 Wis., 530; 58 L. R. A., 748; 91 Am. St. Rep., 934.)

"The term 'property', as used in the Constitution, Articles 1 and 17, forbidding the taking of property for public use without adequate compensation being made therefor, means not only the thing owned, but also every right which accompanies ownership and is its incident." (Gulf, C. and S. F. Ry. Co. *v.* Fuller, 63 Tex., 467, 469; Ft. Worth and R. G. Ry. Co. *v.* Jennings, 13 S. W., 270; 76 Tex., 373; 8 L. R. A., 180.)

"Anticipated Profits. Anticipated profits are not, and cannot be, held and regarded as property in the ownership or possession of him who owns the article out of which profits are expected to flow. The property is one thing, and remains untouched. The profits are *in esse,* and cannot be claimed as property." (Munn *v.* People, 69 Ill., 80, 91.)

"The term 'property', in its broad sense, includes even a franchise, so the word 'property' as used in the statute providing for the taxation of all property not specifically exempted, includes a franchise, and hence a tax on a turnpike is property." (Frankfort, L. and N. Turnpike Road Co. *v.* Commonwealth, 6 Ky. Law Rep., 391, 392.)

"Property in its broadest and most comprehensive sense, includes all rights and interest in real and personal property, and in easements, franchises, and in corporeal hereditaments. That which may be taken for public uses is not exclusively tangible property. Wherever the right of eminent domain exists, whatever exists in any form, whether tangible or intangible, may be subjected to the exercise of this power, and may be appropriated to public use when necessity demands. A franchise is nevertheless a right in the nature of 'property' within the sense that the word is used in the eminent domain law, and no reason is perceived why it could not be condemned for the use of the public. We know of no policy of the law that would forbid the taking of such property for public uses." (Metropolitan City R. Co. *v.* Chicago W. D. Ry. Co., 87 Ill., 317, 324.)

"Water. Water, when reduced to possession, is property, and it may be bought and sold, and have a market value; but it must be in actual possession, subject to control and management. Running water in a natural stream is not property, and never was. The construction of a dam across an outlet of a lake or a river or a creek for the purpose of securing power with which to operate mills or factories is not a reducing of the water to possession, or to control or management, in such a sense as to change its legal character and make it property. If it did, the owner at times might find it difficult to control, especially in case of freshets or floods. He might have trouble in preventing it from being precipitated upon the lands of his neighbors below, and find it unpleasant to respond to them for the damages caused by his property." (City of Syracuse *v.* Stacey, 62 N. E., 354, 355; 169 N. Y., 231.)

It seems to be apparent from these definitions that a property, even in a public utility, is not a mere aggregate of separate structural materials, priced as would be the stock of a shopkeeper, nor can such property be properly confined to a past investment which must be traced out, dollar by dollar, to show how much actual cash has really been put into it. A property, even in a public utility, is a right of possession in a complete entity actively engaged as a co-ordinate whole. This property, as a whole, lives through the ordinary vicissitudes of life, and may have its accretions of value, due to the growth, expansion, and enterprise of the adjacent population, as well as its depreciations, due, among other things, to lessening demand, structure disuse, or changes in the arts. These may be outlined generally, as follows:

ORIGINAL COST.

Depreciations.		Appreciations.
(1) Wear and tear on machinery and plant. Decay.....	Period of growth and usefulness, or of decline and abandonment.	(1) Growth of population and demand on original installation.
(2) Decreased usefulness of plant due to shifting population...		(2) Enlargements and extensions.
(3) Changes in general demand producing obsolescence.....		(3) Growth of population on extensions.
(4) Improvements in the art, requiring replacement.....		(4) Growth of habit, increasing use of service per capita.
(5) Changes required in the source or method of manufacture...		(5) Increasing cost of replacement.
(6) Insufficiency of original installation by reason of increased population.....		(6) Increasing value of real estate.
(7) Checks to growth of population or surrounding industries....		(7) Increasing cost of materials and labor.
(8) Decrease in price of labor and materials.....		(8) Increased business due to enterprising management.
(9) Increased competition.....		(9) Development of new uses for supply or service.
(10) Imprudent expenditures.....		(10) Economies in production effected by good management.

PRESENT VALUE.

A property, therefore, is like an individual. It is born; it goes through its youthful training; it encounters its vicissitudes; it comes to its maturity, or period of usefulness; it expands with the community perhaps; it has its period of decline, and is supplanted by better methods of service or production; eventually it will die, at least so history teaches us. Constantly, however, we find valuers (usually representing what may be called the buyer side of the question) who, through mistaken sympathy, leading to unconscious unfairness, or through ignorance of all sides of the question, or more rarely, it must be regretfully said, through direct prejudice or deliberate intent, would deprive a utility property of its natural growth in value, on the theory that they are dealing here with something other than private property, devoted to the public use. In other words, they would deal with private property devoted to public use, as property the natural growth of which could be checked, or portions of the value of which could be appropriated to the public ownership because of its public use.

Of course, it would be a very interesting and perhaps even profitable inquiry to discuss the question as to whether the Constitution of the United States, as construed by the higher Courts, may be wrong in its theory of property. It might also be of great interest and profit to inquire whether interest is moral, and to raise many other fundamental questions of a like nature. Many intelligent people can be found (and some of them are in valuation work), who would like to see the Constitution revised, at least so far as relates to private property devoted to public use. Such people would not dream of appropriating private property for private use, but are apparently quite willing to appropriate, in part at least, private property devoted to the public use.

The right to hold property, with all its increment of growth, is fundamental to our civilization. Without this right our civilization would vanish. It is to the public interest that this should continue to be so, for the moment we begin to treat private property, devoted to the public use, as public property, then private property will cease to be available for the public uses and the needs of the people, to the detriment of every one. What we are properly striving for, in all the recent movement toward regulation of private property devoted to public use, is not the lessening of the value of that property, but the

correction of abuses and evils which grow out of its improper use or abuse. Wherever, then, we find wide differences of opinion as to the value of a property, devoted to the public use, we will usually find that a large part of the difference is due to differing conceptions as to what it is that is being valued, and differing definitions resulting from that fundamental departure.

If appraisers, and especially engineers, could once get it thoroughly understood that it is not their function to say what is to be appraised—that function belongs to the law, and such points are fundamentally determined by the Constitution of the United States, as interpreted by the Supreme Court—then most of our troubles and confusion in appraisal work would be over.

The Right of Regulation.

The leading case in the Supreme Court of the United States upholding the power to regulate the rates of public utilities was handed down as far back as 1876, and is based on the proposition that one who devotes his property to a public use:

"In effect grants to the public an interest in that use, and must submit to be controlled by the public for the common good to the extent of the interest he had thus created.

"He may withdraw his grant by discontinuing the use, but so long as he maintains the use he must submit to its control." (Munn *vs.* Illinois, 94 U. S., 43, 24th Law Ed.)

It is interesting to examine historically the widening acceptance which has been given to this principle, even by the Courts themselves. Little by little it has been extended from pure monopolies into the domain of quasi-monopolies, and finally to public utilities that are competitive, such as lighting, heat, and power; so that now it is virtually conceded that all business in which public grants are necessary is subject to public regulation. It is now coming to be well understood that a successful public utility property, to give good service, should, as a rule, be a monopoly. The old idea which prevailed a generation ago, and was recognized by the laws of such States as California—that it was a good thing to have rivalry in public service corporations—has passed, and we recognize that a regulated monopoly is, all things considered, by far the best method of conserving our resources and serving ourselves.

When, however, we come to value a monopoly as a property, and especially where a monopoly is subjected to rate regulation, we appear to come to a difficulty that its value may depend, to a large extent, on the rates, and as the proper rates are obviously dependent in part on the value, we seem at first glance to be reasoning in a circle. This difficulty, however, is not as great as it appears, because on closer investigation we shall find that, when a property consists largely of a physical plant, we can find a proper value for the property, even though its value depends in part on a regulated rate of return. This is also possible where the rates must afford a fair return, which rate of return, however, must be assumed in advance. In other words, where there is a fixed physical plant and a fixed fair rate of return, a definite value results.

In valuing a regulated monopoly or partial monopoly, we cannot, of course, proceed as we would with an ordinary business, fluctuating with its good-will, nor can we properly capitalize existing income independent of physical plant. We are, therefore, evidently limited to methods in which value is not wholly dependent on income, because the income is to be regulated. We are usually obliged, therefore, to reason from the basis of the physical property, plus the cost of financing it into proper and remunerative income.

A great deal of exception has been taken to this embarrassing condition, because it at once does away with a most common and natural method of arriving at value, that of capitalizing income. It is difficult, however, to see how this can be overcome, so long as rate regulation is a fundamental precedent to a valuation.

The Supreme Court of Wisconsin, in the recent Appleton Case (142 Northwestern Reporter, 476, May 31st, 1913), evidently feeling the embarrassment of the situation, says:

"The commercial value of the business in full operation and entitled to charge reasonable rates for its service must, however, be considered as approximating the compensation which should be allowed for the property; in other words, the sum which the business should be capitalized for, in order that the owner should receive a reasonable return on the investment when the business is conducted with reasonable business skill, and charges such reasonable rates for service as the law permits."

This rule would bring permissible net income, or, as the English authorities put it, "maintained and maintainable net income," into a

position of prominence at once, were it possible to define maintained and maintainable income, or, "such reasonable rates for service as the law permits," entirely aside from all consideration of the property devoted to the public use itself, but the Wisconsin Supreme Court nowhere else in its opinion gives us any clue as to how this "reasonable rate" is to be defined, and ends by approving the findings of the Commission, based on examination of the physical property in connection with other evidences of value.

There seems to be no escape from the conclusion that, so long as rates of return are to be regulated, they cannot be used as a sole foundation for ascertaining value. Some other and more devious path is forced on our attention, in which the importance of the return is, if not altogether eliminated, at least so minimized as to lose its preponderating influence.

The Starting Point.

An examination of their decisions will show that the Courts have reached a definite conclusion that the proper interpretation of the Constitution requires them to insist on two essentials:

(*a*) That what is to be valued is the "property."

(*b*) That what is to be ascertained is the present value of this property.

This has compelled the Courts to require such an investigation as will present to them all the factors necessary for the determination of the present value of the property devoted to the public use.

The following is an extract from Minnesota Rate Cases, 230 U. S., 352, 434:

"(1). The basis of calculation is the 'fair value of the property' used for the convenience of the public. Smyth *v.* Ames, *supra* (p. 546). Or, as it was put in San Diego Land and Town Co. *v.* National City, *supra* (p. 757), 'What the company is entitled to demand, in order that it may have just compensation, is a fair return upon the reasonable value of the property at the time it is being used for the public.' See also San Diego Land and Town Co. *v.* Jasper, *supra;* Willcox *v.* Consolidated Gas Co., *supra.*

"(2). The ascertainment of that value is not controlled by artificial rules. It is not a matter of formulas, but there must be a reasonable judgment having its basis in a proper consideration of all relevant facts. The scope of the inquiry was thus broadly described in Smyth *v.* Ames, *supra* (pp. 546-547): 'In order to ascertain that value, the

original cost of construction, the amount expended in permanent improvements, the amount and market value of its bonds and stock, the present as compared with the original cost of construction, the probable earning capacity of the property under particular rates prescribed by statute, and the sum required to meet operating expenses, are all matters for consideration, and are to be given such weight as may be just and right in each case. We do not say that there may not be other matters to be regarded in estimating the value of the property. What the company is entitled to ask is a fair return upon the value of that which it employs for the public convenience. On the other hand, what the public is entitled to demand is, that no more be exacted from it for the use of a public highway than the services rendered by it are reasonably worth.'"

Ames *vs.* U. P. Railway, 64 Fed., 165.

San Diego Land and Town Co. *vs.* National City, 74 Fed., 74 (189) (Ross): "In my judgment it is the actual value of the property at the time the rates are to be fixed that should form the basis upon which to compute just rates, having at the same time due regard to the rights of the public and to the cost of the maintenance of the plant and its depreciation by wear and tear."

Cotting *vs.* K. C. Stock Yards (1897), 82 Fed., 850, 854. "If improvements have been made in the vicinity of the property, the growth of the city or town where it is located, the building of railroads, the development of the surrounding country, and other like causes give property an increased value, the owner cannot be deprived of such increase by legislative action which prevents him from realizing an income commensurate with the enhanced value of his property."

Smyth *vs.* Ames, 1898, 169 U. S., 466; 18 Sup. Ct., 418 (Justice Harlan). "We hold, however, that the basis of all calculations as to the reasonableness of rates * * * must be the fair value of the property being used by it for the convenience of the public."

Willcox *vs.* Consolidated Gas Co., 212 U. S., 19-52 (1909); 29 Sup. Ct., 192-53.

This last case is an interesting one, as it applies this line of reasoning to some very extreme conditions, and it is a recent case. It may be well to quote from the Circuit Court (157 Fed., 849), from which the appeal was taken, more fully, as follows:

"It is impossible to observe this continued use of the present tense in these decisions of the highest court without feeling that the actual or reproductive value at the time of inquiry is the first and most important figure to be ascertained, and these views are amplified by San Diego Land Co. *v.* Jasper (C. C.), 110 Fed., at page 714, and Cotting *v.* Kansas City Stock Yards (C. C.), 82 Fed., at page 854,

where the subject is more fully discussed. Upon reason, it seems clear that in solving this equation the plus and minus quantities should be equally considered, and appreciation and depreciation treated alike. Nor can I conceive of a case to which this procedure is more appropriate than the one at bar. The complainant by itself and some of its constituent companies has been continuously engaged in the gas business since 1823. A part of the land in question has been employed in that business for more than two generations, during which time the value of land upon Manhattan Island has increased even more rapidly than its population. So likewise the construction expense, not only of buildings, but of pipe systems under streets now consisting of continuous sheets of asphalt over granite, has enormously advanced.

"The value of the investment of any manufacturer in plant, factory, or goods, or all three, is what his possessions would sell for upon a fair transfer from a willing vendor to a willing buyer, and it can make no difference that such value is affected by the efforts of himself or others, by whim or fashion, or (what is really the same thing) by the advance of land values in the opinion of the buying public. It is equally immaterial that such value is affected by difficulties of reproduction. If it be true that a pipe line under the New York of 1907 is worth more than was a pipe line under the city of 1827, then the owner thereof owns that value, and that such advance arose wholly or partly from difficulties of duplication created by the city itself is a matter of no moment. Indeed, the causes of either appreciation or depreciation are alike unimportant, if the fact of value be conceded or proved; but that ultimate inquiry is oftentimes so difficult that original cost and reason for changes in value become legitimate subjects of investigation, as checks upon expert estimates or bookkeeping inaccurate and perhaps intentionally misleading. *Cf.* Ames *v.* Union Pacific R. R. (C. C.), 64 Fed., at pages 178, 179. If 50 years ago, by the payment of certain money, one acquired a factory and the land appurtenant thereto, and continues to-day his original business therein, his investment is the factory and the land, not the money originally paid; and unless his business shows a return equivalent to what land and building, or land alone, would give if devoted to other purposes (having due regard to cost of change), that man is engaged in a losing venture, and is not receiving a fair return from his investment, *i. e.*, the land and building. The so-called 'money value' of real or personal property is but a conveniently short method of expressing present potential usefulness, and 'investment' becomes meaningless if construed to mean what the thing invested in cost generations ago. Property, whether real or personal, is only valuable when useful. Its usefulness commonly depends on the business purposes to which it is or may be applied. Such business is a living thing, and may flourish

or wither, appreciate or depreciate; but, whatever happens, its present usefulness, expressed in financial terms, must be its value.

"As applied to a private merchant or manufacturer, the foregoing would seem elementary; but some difference is alleged to exist where the manufacturer transacts his business only by governmental license —whether called a franchise or by another name. A license, however, cannot change an economic law, unless a different rule be prescribed by the terms of the license, which is sometimes done. No such unusual condition exists here, and, in the absence thereof, it is not to be inferred that any American government intended, when granting a franchise, not only to regulate the business transacted thereunder, and reasonably to limit the profits thereof, but to prevent the valuation of purely private property in the ordinary economic manner, and the property now under consideration is as much the private property of this complainant as are the belongings of any private citizen. Nor can it be inferred that such government intended to deny the application of economic laws to valuation of increments earned or unearned, while insisting upon the usual results thereof in the case of equally unearned, and possibly unmerited, depreciation.

"I think the method of valuation applied by the report to land, plant, mains, services, and meters lawful."

On appeal to the United States Supreme Court, the above position of District Judge Hough was approved. Justice Peckham, in delivering the opinion of the Court, says (212 U. S., 19, 52; 29 Sup. Ct., 192; 53 L. ed., 382, January 4th, 1909):

"And we concur with the court below in holding that the value of the property is to be determined as of the time when the inquiry is made regarding the rates. If the property, which legally enters into the consideration of the question of rates, has increased in value since it was acquired, the company is entitled to the benefit of such increase. This is, at any rate, the general rule. We do not say there may not possibly be an exception to it, where the property may have increased so enormously in value as to render a rate permitting a reasonable return upon such increased value unjust to the public. How such facts should be treated is not a question now before us, as this case does not present it. We refer to the matter only for the purpose of stating that the decision herein does not prevent an inquiry into the question when, if ever, it should be necessarily presented."

It is apparent, from these opinions, that there is no escape from the conclusion that in all ordinary cases we must value a public utility as a "property" and find its value as of to-day. Nothing short of a reversal of its own opinion by the Supreme Court, a new Consti-

tution for the United States, a revolution, or what would be (in the writer's opinion at least) infinitely worse, the recall of judicial opinion, could alter this present status.

If, therefore, we must value a utility as a property, and value it now, it is quite obvious why the Courts have concluded that reproduction cost, less depreciation, of the existing property (or, as we will call it for the sake of brevity, "reproduction") is usually a leading and most important line of evidence to aid in arriving at value. The Courts do not suggest the neglect of any other lines of evidence, but, under normal circumstances, they place weight on such evidence as tends to show the value of the property now.

The general trend of recent decisions has been to make reproduction cost methods a controlling and important line of evidence as to value under normal conditions.

In a Minnesota rate case—Steenerson *vs.* Great Northern Railway, 69 Minn., 353, October 20th, 1897—the Court said:

"Then the burden is on the railroad company to show that the rates fixed by the Commission are unreasonable, and for this purpose the original cost of the road, the amount of its present fixed charges, and its history, are material only so far as they show what it would now cost to reproduce the railroad."

In 1911, the later Minnesota rate cases, Shepard *vs.* Northern Pacific Railway Co., 184 Fed., 765, April 8th, 1911:

"The master rightly decided that the cost of reproducing this property new was a more rational and reliable measure of its real value than the original cost of its acquisition and construction or the market values of the stocks and bonds of the companies, and upon that basis he made his findings."

In San Diego Land and Township Co. *vs.* National City, 74 Fed., 79, May 4th, 1896, the Court says it is "Present value", and, on appeal, Justice Harlan refers to "reasonable value of the property at the time it is being used for the public." (174 U. S., 739.)

In the Consolidated Gas Case *vs.* the City of New York, 157 Fed., 849, Judge Hough said:

"In every instance, however, the value assigned in the report is what it would cost presently to reproduce each item of property in its present condition, and capable of giving service neither better nor worse than it now does. As to all the items enumerated, therefore, from real estate to meters, inclusive, the complainant demands a fair

return upon the reproductive value thereof, which is the same thing as the present value, properly considered. To vary the statement: complainant's arrangements for manufacturing and distributing gas are reported to be worth the amounts above tabulated if disposed of (in commercial parlance) 'as they are.'

"Upon authority I consider this method of valuation correct. What the court should ascertain is 'fair value' of the property being used (Smyth *vs.* Ames, 169 U. S., 546); the 'present' as compared with 'original' cost; what complainant 'employs for the public convenience' (169 U. S., at page 547); and it is also the value of the property at the time it is being used (San Diego Land Co. *vs.* National City, 174)."

The Courts are extremely cautious not to commit themselves to reproduction methods, as a rule, for finding value, and this is because they see clearly that exceptional conditions might make the evidence of reproduction methods at times misleading and dangerous. As a matter of practical inquiry, however, under the conditions as ordinarily met with, and in the great majority of valuation cases, the Courts pay special attention to reproduction methods, and the largest portion of the testimony in such cases is usually directed to this line of evidence, for the very good reason that, unless abnormal conditions are present, it is the method which will most nearly disclose the value of the property as of to-day.

Let us inquire further what general procedure we may adopt in valuation work to be in harmony with the reasoning of the Courts on this subject.

Practical Methods of Utility Valuation.

The function of valuing a public utility property consists essentially of two distinct operations:

First.—The collection of all the facts and evidence tending to throw light on the question of value; and

Second.—The judicial function of weighing the evidence, apportioning to each line of evidence its relative degree of importance, and reasoning from this summation to the broader question of value.

In valuation work, much confusion of thought arises from the very human anxiety to reason on the broader question of value before all the data are accumulated, properly digested, and placed in their proper perspective.

The facts and evidence desirable for a full understanding of the value of a utility property are generally as follows:

First.—The cost to replace the property at the present time as a going concern.

This line of investigation requires:

(*A*) An inventory of the present existing physical property, used and useful for the purpose of the utility.

(*B*) A statement of its earnings and expenses for a preceding series of years, not less than five, and preferably ten or more.

(*C*) Computation of the cost to replace the property now, and reproduce its income as a going concern, all in a way which is humanly possible.

(*D*) An estimate of the loss of value in the existing property, by reason of age, changing requirements, advances in the arts, or use.

Second.—The market value of the securities of a property, where a broad and representative market for such securities can be said to exist.

Third.—The value of other properties similarly situated, where such value has been carefully and fully determined. This can be used only as a general check, however.

Fourth.—The conditions which surround the particular property to be valued, such as the character of population, its past growth and present business enterprise; the presence or absence of judicious management of the utility property, and its conservative extension; freedom of the property from mishaps; the value of the service to the individual consumer; competition, if any, and possible future contingencies arising both from changes in public demand or substitution of other service more acceptable to the population; and, finally, the legal status of the property, and attitude of the public and its representatives toward it.

Fifth.—The Courts hold that, where past cost can be obtained, it is competent evidence. The fact that it is competent does not mean that it is controlling, and does not indicate the weight it should have. What weight it should have in

any case depends on whether or not the conditions when the past cost was incurred are the same as the conditions at the date of the valuation. If they are, it is valuable evidence. In proportion as the conditions differ, the weight to which this testimony is entitled grows less. It is for this reason that recent costs, which presuppose unchanged conditions, are treated as valuable factors, while ancient costs are usually valueless.

The judicial reasoning which should follow the compilation of these lines of inquiry is as follows:

First.—To be assured that the evidence is without material error.

Second.—To determine the amount of credence to give to the witnesses who introduce evidence. This may be based largely on their practical experience in the matters in hand, as well as their conscientiousness and freedom from bias.

Third.—To determine that each independent line of evidence introduced is in itself logical and complete, and is not confused with any other line of evidence, such as the mixing up of past cost with present cost to reproduce, etc.

Fourth.—To decide what weight should be given to the various lines of evidence introduced.

Fifth.—To determine in each case the extent to which each line of evidence is a material factor in measuring value, and if it is not such a factor, to reason why not.

Sixth.—To determine in particular whether the cost of reproduction, including the cost of reproducing the present income of the company, is or is not the most important factor in reaching a sound conclusion as to value.

Seventh.—To conclude finally on the value, from a broad and adequate review of all the facts, with an open mind, in a judicial manner, and as a matter of common sense.

Eighth.—To check the value so obtained by such lines of inquiry as will properly be of aid.

In weighing evidence as to value, it is important to remember:

First.—That value is, after all, a matter of intelligent opinion, based on all the ascertainable facts with special reference to the conditions of the case in hand.

Second.—That cost is not usually coincident with value.

Third.—That the Courts uniformly have insisted that it is the present value, or value now, that must control.

Fourth.—That reproduction is usually the most direct line of evidence bearing on value now.

Fifth.—That cost now is not necessarily value now, for it is easily conceived that, under many circumstances, a plant may be worth more or less than even the cost to reproduce it now.

Sixth.—That the weight to be given the evidence of individual valuers is in direct proportion:

(*a*) To the extent of their direct past practical experience;

(*b*) To their breadth of view and study in callings other than their own profession affecting valuation work;

(*c*) To their character and standing as fair and unbiased men, used to considering both sides of the questions at issue in an impartial manner.

Reproduction.

The foregoing discussion, quoted opinions, and outline of valuation procedure, demonstrate why reproduction has assumed its importance in public utility valuation. It has not been originated by engineers to torment the Courts, but it has been concluded by the reasoning of the Courts to be a logical and important line of evidence, and the Courts have compelled the Engineering Profession to work out its details in a practical way, and in a manner that is humanly possible.

In considering reproduction, however, we are confronted, first of all, by the fact that the more fully it is examined the more it is seen to be a hypothetical proceeding, using this term in its legal sense, Nothing about it is so real as the results to the owner. The more it is studied the more it must be conceded that reproduction is purely a conceptual forecast in a most difficult and specialized art—that of financing and building especially designed public works for distinct kinds of public service. Even the art of constructing public service plants is comparatively new; the number of engineers specially skilled in the broader aspects of such arts is relatively few; and the mature and experienced engineers in such specialties are fewer still. It is quite obvious that in the immature thought of impractical and in-

experienced minds, reproduction can be made absurd to the point of ridicule, and, even in the hands of an experienced, painstaking, and unbiased investigator, it is questionable whether the full, proper, and natural sequence of events necessary to the hypothetical rebuilding of visible property can always be properly and intelligently thought out with any reasonable degree of thoroughness and proper prophecy, without omission of matters which would probably unexpectedly occur in any actual procession of events.

Conceptual Processes.

Let us see what it is that the Courts have asked us to do when we are made to undertake the task of reproducing. Having familiarized ourselves with the existing property which is to be valued, we must, in imagination, as a prolonged conceptual process, retrace, step by step, every feature of the procedure that would have to be taken if that property were completely wiped out, and we were responsible for the task of entirely rebuilding it in a reasonable length of time and in a manner which is humanly possible. Should we unconsciously omit one important step necessary to that rebuilding, we will fail to reach the full cost. Being in possession of retrospect, we are constantly subject to the temptation to substitute an easy and virtuous hindsight for that real lack of foresight which would be our condition in actual life and under ordinary conditions. If we do full justice to the procedure, we must trace two lines of human endeavor, that is, the mental labor as well as the physical labor which produced the result before us. Mental endeavor will include the development of the project and the preliminary steps of promotion. This must include the necessary time and pains that would naturally be taken to see that the project is practical, the time and attention necessary to negotiate the franchise, investigate the methods of service, and estimate the preliminary work. We must at every step of the way outline to ourselves the necessary lengths of interlapsing time to do all these things, as well as the amount of labor to design, contract for, and actually build each structure. Much of our cost will be entirely dependent on the length of time we assume for these practical operations. It is quite certain that the most trained imagination, practically acquainted with similar construction, will not always entirely succeed in redeveloping every detail involving expense

in such a procedure. The Courts, in advocating reproduction as a valuable line of inquiry, have probably thought that a hypothetical reconstruction was simple. At first glance it would appear simple; so many pounds of rail at so much, so many ties at so much, and total so much. Any one coming to the task of reproducing a property in this spirit has singularly misconceived the extent and complexity of the problem before him.

The Sidewalk Illustration.

The fallacious attitude of many estimators can best be shown by a simple illustration of sidewalk construction. You sit in your library window with your little boy and watch the construction of a sidewalk across the street, and you ask your boy how sidewalks are built. In all probability he will reply, with his eye on the scene, "Why, they take crushed stone and cinders and sand and cement and mix them up and spread it out to dry between planks that keep the edges straight; then they tamp it all down, smooth it over, leave it to dry, and when it is done they clean up and go away."

Now, this is really about all the average grown person sees of engineering work. Even some judges and economists would hardly give a fuller answer. They might add that the sidewalk costs a certain sum per square foot, because the sidewalk contractor received that sum, and that estimate of cost would be the general impression of a good many mature people as to the cost of sidewalks.

Let us analyze the matter a little further. Assume that you are familiar with municipal engineering, and you will find in your mind's eye vastly more things that have to be done than your boy could see. A petition from the property owners has to be presented to the common council of the city, with the signatures of the majority of the frontage owners attached thereto. The council perhaps sends an inspector, who reports on the matter. A committee of the council deliberates and reports back favorably to the council. An ordinance has to be drawn by the law department of the city, the engineering department submits an estimate for the cost of the work, and the council then passes the ordinance. A warrant is issued from the proper court for the spreading of the assessment and commissioners are appointed who apportion the tax and make their report. A hearing is held at which objectors may appear. The assessment is perhaps

finally confirmed, and a warrant issued to the county or city collector, the tax bills are sent out, and the moneys are received by the treasurer.

In the meantime, the city engineering department has drawn up specifications for the work, describing minutely just what is to be done, the kind of material to be used, and its method of mixing and laying. Notices are inserted in the newspapers calling for bids. Contractors make their estimates and appear at the letting; the bids are received, opened, and tabulated; a report is made by the engineer to the council; and the work is thereupon let to the lowest bidder. A contract is drawn up by the law department, bonds of a proper amount are deposited, and the contract is signed. In the meanwhile the city engineer sends an assistant who stakes out the established grade which had heretofore been fixed by the council from surveys of the city by the engineering department. An inspector is appointed to see that the specifications and contract are complied with. In the meantime the contractor had figured out the necessary quantities of material, purchased the proper quality, and had hauled it to the work. He then engaged a mason and helpers, a foreman and laborers, and then—your little boy saw them appear on the street to do the work.

Now, what was the real cost of that sidewalk? Certainly the city treasurer's books do not show it. Did the engineer in charge know? Did the contractor know? Did your little boy know? Did any one ever really know?

Public Misconceptions.

So it is with the average public utility valuation. The public thinks of it as a list of visible material which must simply be priced, and when the engineer talks about preliminary expense, length of time, methods of construction, plant financing, overhead charges, developing the business, and the like, the public thinks he is trying to inflate the valuation by what it likes to call "intangible" items.

The fact is, as has recently been well emphasized by M. E. Cooley, M. Am. Soc. C. E., in an address before the Annual Meeting of the Western Society of Engineers,* that neither the Courts nor the public have any clear idea of the real cost of building up a property, and it is a public duty for the Engineering Profession to point out all the necessary elements of cost which would be incurred in a real enter-

* *Journal*, Western Soc. of Engrs., January, 1914, p. 1.

prise, and to insist that hypothetical reproduction estimates must be made in a manner which is humanly possible and practically feasible, such as would be the case in real life and in line with real practical experience.

Most attempts at hypothetical reproduction produce estimates that arrive at a less cost of reproduction than would be found necessary in real actual building, by reason of the before mentioned tendency to omit minor items, overlook necessary auxiliaries, or fail to appreciate all the contingencies that are likely to occur in an actual undertaking. All engineers realize that the less we know about a given line of building work, the more apt we are to underestimate it, and almost every one who has built a house can recall how much they underestimated the final cost, and why.

Reproducing the Income.

When we reproduce a property, we must reproduce all of the property there is; that is, we must reproduce it up to its present state of efficiency, including the cost of financing the plant to the point where it has income and is paying a fair return. This is so astonishingly simple as a proposition that one constantly wonders why it should be disputed, yet, as a matter of fact, few appraisers have attempted to reason it out logically or compute properly the expense of financing a plant on a going basis, and the average estimator stops short when he gets to the end of his list of prices of visible things and wonders what he shall do next. It took a high Court ruling in the Kansas City Water-Works case, twenty years ago,* to compel the inclusion of the cost of reproducing the plant to an income-paying basis, and, ever since that decision, "going value" has been the bogy of valuators, utility commissions, and municipalities.

"Going value" is an unfortunate name. The Courts have attached those words to that part of the reproduction method which has to do with reproducing the financing of the physical property on a paying basis. As commonly used, it is nothing more or less than a necessary part of the reproduction process; as a principle, it is entirely simple and easy to understand.†

---

* National Water-Works Company *vs.* Kansas City, 62 Fed., 853; 10 C. C. A., 653; 27 L. R. A., 827; 27 U. S. App., 165; July 2d, 1894.

† See "The Going Value of Water-Works," by Leonard Metcalf and John W. Alvord, Members, Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXIII, p. 326 (1911); also "Notes on Going Value and Methods for its Computation," by John W. Alvord, *Proceedings*, Am. W. W. Assoc., 1909, p. 184.

As reproduction is a cost method, and as cost is not necessarily value, the term "going value", generally used to designate the completion of the cost-of-reproduction method, is a misnomer. It would be better to modify the term to "going cost", when speaking of that part of the reproduction which it describes.

When we have completed our reproduction-cost estimates, including going cost, and when we have reasoned from this line of evidence and other lines of evidence to the value of the property, then we might properly use the term "going value" to designate the entire property value as a going concern, for then we are talking about value and not about cost.

A great deal of perplexity in valuation work and valuation discussion arises from just such confusion of terms as is here described, and this perplexity will continue until engineers get more clearly defined notions of valuation work, for it appears to be necessary to use brief descriptive terms in such discussions.

Reproduction A Cost Method.

A great many estimators, and most of the utility commissions, use the reproduction method as though it were a sort of a formula for the final determination of value. In other words, they unconsciously assume that they are completing their valuation, step by step, with each item of the reproduction, and get afraid during the process that the final result will not be exactly what they want; that is, they fear it will lead them somewhere where their reason would not fully approve. All this would be obviated if the estimator had clearly in mind the simple proposition that reproduction is a cost method, and, as such a method, when completed it may or may not be the real value. When one has completed the reproduction estimates, he always has the right to reason whether it furnishes him with a good approximation of the value. This is why the Courts keep reiterating that other things should be taken into consideration, such as past cost, for instance, where it is available, market value where it can be found, and, more particularly, the surrounding conditions, such as the need for the service, the value of the service to the consumer, the adequacy of the service, and such other factors as have been heretofore mentioned. All these surrounding conditions, with the proper analysis, will show whether or not the reproduction cost method can be safely used, and

if not directly used, what modifying influences would properly be taken into consideration.

If, for instance, a plant has recently been built in a town the chief industries of which have unexpectedly come to an end so that the town will inevitably depopulate, then the cost of reproducing such a plant is obviously not a proper measure of its value; or, if a new and better method of service be suddenly discovered or is soon likely to be discovered through new invention or change in the arts, then a similar result will ensue. On the other hand, if a plant is properly built, with reasonable skill, in a growing city, and has perhaps the most desirable kind of service, and is without engineering or financial errors, or dishonesty of management, or bad judgment in its financial development, then the value of that property may be even greater than would be indicated by the reproduction-cost method.

This matter of disassociating value from cost is one of the greatest difficulties that the engineering student of appraisal work encounters. It is so common an experience to most engineers to think of value as synonymous with cost, that the possibility of these two things being at times unequal is only received by the average mind with something akin to a wrench.

When an appraiser gets clearly in mind what reproduction is, that it is a cost method with many limitations, and that, although it is usually only one of the lines of evidence which should be taken into consideration, all difficulties with the logical details of reproduction will naturally and easily be resolved by the application of a little careful reasoning. It will be obvious that any doubts, for instance, about including pipe under pavements, interest during construction, ownership of services, overhead charges, preliminary expense, and going cost, arise mainly from the fact that the valuer has no clear idea of what he is doing or how it is to be useful when done. The valuer should never be afraid of a logical reproduction, but he should fearlessly and conscientiously follow it through to the logical end, not mixing it at any point with past cost, or deviating from the natural requirements of a practical and actual reconstruction in any way. When reproduction is thus carried out, the valuer should set it aside as one of the most important lines of evidence, and finally review it in connection with other lines of evidence and all the surrounding circumstances, many of which, though affecting value, cannot well be expressed in figures

at all, or can only be expressed partly in figures. His final conclusion as to what is the fair, just, and equitable value of the property in question, all things considered, should be reasoned out in the broadest kind of a way.

Summary of Reproduction.

In reproducing a plant and property, therefore, we may summarize the following principles of procedure as in accordance both with the opinions of the Courts and as generally agreed to by those appraisal engineers of long experience in valuation work:

First.—The reproduction should be along lines that are humanly possible, and in accordance with practical experience.

Second.—It is entirely a hypothetical and conceptual process from beginning to end, and, therefore, to be practically useful, must be founded on a long and wide practical experience.

Third.—It is to be based on a practical working plan, in which the time adopted for the proper procedure is one of the most important elements.

Fourth.—A hypothetical reproduction, to be practical, must be predicated on a reasonable construction and development period in the near future.

Fifth.—The costs for this near future must be based on the prices of the recent past, just as any engineer entering into any new work determines the probable near future costs from past experience.

Sixth.—The reproduction is not complete until the plant is financed on a paying basis, *i. e.*, earning a fair return.

Seventh.—To use this reproduction as a measure of the present plant, the depreciation of the existing property must be computed and allowed for.

Eighth.—Reproduction is a cost method, and, as such, may or may not be of value. When reproduction is completed up to a paying basis for the property, then, and not until then, have we a right to reason whether this cost method is a good measure of value.

Ninth.—If a plant is carefully and honestly built, if it serves a need in the community in the best possible manner, and if there is no better or less expensive service, then the cost of reproduction must of necessity be the least possible value that can be put on the utility, but the real value may often be in that case more than the reproduction cost.

Tenth.—On the other hand, if a plant has been recklessly overbuilt, or if the need for its service has diminished, or changes in the arts require its early abandonment, then the cost of reproduction will largely exceed the true value, unless materially reduced by an adequate allowance for depreciation of a general nature.

Past Cost.

It is interesting to note the tendency of the newer public utility commissions to emphasize past cost data as of major importance, and substitute it in whole or in part for reproduction cost wherever possible. Almost all appraisers have been through this experience. Later and more mature consideration generally converts them to giving more weight to the reproduction process. This tendency to emphasize past cost is not in accord with the opinions and reasoning of the higher Courts, which are constantly pointing out that it is the value of the property now that must be sought, and, though the Courts do not deny that past cost is a proper and suitable line of inquiry, they very properly insist that it is only useful because it may throw some light on the value of the property now. This line of thought of the Courts may be summarized, as follows:

First.—Past cost often does not include all the actual cash cost incurred in promoting the enterprise, nor does it usually show the deficits which have occurred below a proper revenue from time to time.

Second.—It lacks any indication as to how the property has appreciated, by reason of its own growth and, as well, the growth of the community in which it is located, or the growth of demand for its product from a given community.

Third.—It usually contains the cost of all obsolete structures, and, as found on the books, has usually no allowance for depreciation.

Fourth.—There is nothing to show the hazards in the original installation. Plants were often originally built when enterprises of a similar nature were new and untried, when the community was small, and the value of public service was unknown and unappreciated.

Fifth.—Markets for special classes of supplies, machinery, and labor, have fluctuated widely, and in some cases radically, so that any attempt to reason present cost from past cost must inevitably be a task of great speculative difficulty.

Sixth.—Granted that we could properly compute all the depreciations and the appreciations, and could determine correctly the proper deficits in revenue and make proper allowances for changes in the markets for material and labor, and compute correctly the hazards and cost of money under the original circumstances, we would not even then have a measure of value, but only a measure of cost, which might correspond with reproduction cost now, but this might or might not be the value of the property, as the case might be.

It is seldom possible to find an accurate and complete record of past cost, intelligently kept on a proper accounting basis, with proper separation of operating from capital account.

When the past cost of a public utility company is available and can be found from the books, it usually appeals strongly to the buyer side of the question, for the simple reason that it is often less in amount than the present value of the property, and usually less than the actual cost and the present cost by reproduction methods. Cases arise, however, where past cost is much greater than present value or replacement cost.

Undoubtedly, Courts, economists, and engineers would all like to have as definite and satisfactory a method on which to reason value as past cost would seem to be on the face of it, but, unfortunately, its face appearances are most misleading, for if we must find the value of the property now, that value is probably less controlled by past cost than any of the other cost methods from which the value can be reasoned.

The procedure adopted by some utility commissions, of utilizing reproduction methods for the structure cost, and adding to this amount past deficits in operation to produce a total, has always seemed to the writer to be singularly devoid of any rational basis of explanation, for it mutilates the reproduction of a property so as to render it illogical and incorrect. Some comments on this procedure may be summarized, as follows:

First.—It appears to be the result of a timidity about the reproduction method, which it is believed would not exist if it were fully understood that reproduction cost is not an arbitrary measure of value.

Second.—It leaves entirely uncompleted a valuable line of inquiry, that of reproduction logically carried out to its logical completion.

Third.—It does not encourage the summing up of the real present reproduction cost and the actual past cost as two entirely distinct and valuable lines of evidence, each to be used as a basis for further investigation and reasoning.

Fourth.—It appears to have resulted from an over-anxiety to reason about value before all the cost evidence is in hand.

Fifth.—It tends to discourage the adequate consideration of important factors which influence value, and which cannot always be well expressed in figures, and this effect is caused by reasoning on value at too early a stage in the proceedings.

Sixth.—It would seem that the consideration of past deficits is given too much prominence, because their inclusion in present value puts a premium on poor judgment or misfortunes in the past. The best managed and most valuable properties, under this method, would show the least value, and the most unfortunate and worthless would show up the best.

Seventh.—It would appear that past deficits belong to the past cost line of evidence, and are properly considered here, and not in reproduction cost evidence.

Eighth.—It is quite impossible to see how deficits of past operating cost have anything to do with the cost of financing a physical property into a paying income now.

Market Value.

Although the Courts have said that market value is one of the elements to be considered in valuing a utility property, as a matter of practical application, it is found that a broad and representative market for the securities of a utility company is not usually found, except in the case of the railways and the larger utilities in our great cities. In most of the smaller utilities a general market either does not exist for the property as a whole, or is so restricted as to be an unsafe guide as to its value.

In the process of reproduction, however, we apply the principles of market value indirectly. We may not find that the value of the property, as a whole, may be determined in this way, but by the process of an imaginary re-creation we may find the market value of materials and labor, machines and appliances, and so utilize market

value indirectly for at least a portion of the more tangible parts of the property.

In the larger utilities and the railways, where stocks and bonds are regularly listed and broadly dealt in, market value has more meaning, and should be reviewed, bearing in mind, however, its fluctuating character and its attempted prophetic indication of future rather than present values.

The market value of to-day is almost always built up on the hopes or fears for the morrow, and thus, to a large extent, may consist of too much optimism or pessimism for real present usefulness.

Market values, as indirectly introduced in the reproduction method, are also productive of embarrassment, for it is certain that the value of utility property, as a whole, does not fluctuate with the variations of the material and labor market on the detailed items of which it is composed, and this should always be remembered when the final reasoning is in progress.

On Reasoning From Cost to Value.

By far the most important part of the matter of determining a just and reasonable value of a property lies in summing up all the evidence obtained from cost or other methods, and reasoning from these facts and estimates to the broader question of value of the property, as a whole.

Singularly enough, this important phase of valuation work has not been generally appreciated by engineers, but it has been constantly emphasized or discussed by the Courts. Most engineers assume that the process of valuing is finished when the cost evidence is complete, and by that time they usually have become so beclouded by the mass of detail through which they have struggled that they are often mentally unfitted to undertake the broader and more important responsibility of reasoning to the final result.

It is true that if engineers are seriously to value a property they must familiarize themselves thoroughly with the details of that property, by carefully working out such lines of cost evidence as are necessary, but it by no means follows that they must neglect the broader aspect of the question when this preliminary and detailed work is done.

The general summation of value, from all the surrounding facts, is the part of the problem where the mental methods of the broad-minded business man and financier come into play, and it is precisely here that the business man becomes impatient with the Court and the engineers. Large buyers of public utility properties purchase such properties without any preliminary replacement estimates whatever. What a business man generally wants to know is the character of the city, the needs of the population, its enterprise and probable future growth, the presence or absence of business and manufacturing industries, and, as well, any probable competition or probable changes in demand. He wants to know the gross and net revenues actually existing. He will look carefully at the possibilities of economies, and especially at the probability of increasing the demand for the product or service. From these lines of information, and possibly comparative per capita costs of similar enterprises elsewhere, he will rapidly frame up in his mind a maximum and minimum value within which he can afford to trade for the plant, and the point at which the willing seller meets the willing buyer finally fixes the value of the plant in terms of money. Now, what appraisal work lacks to date is more of this kind of final review, well reasoned out after all the cost lines of evidence are in and complete.

To a man of affairs, accustomed to this kind of rapid valuation, the methods of the Courts, the appraisers, and the utility commissions look quite absurd—how absurd may be well indicated here by a rude illustration:

Appraising A Horse.

When an ordinary farmer or stockman wants to purchase a horse, he runs over in his mind the prices at which, ordinarily, horses have been selling, the uses and needs he has for this particular horse, the earnings the horse can make for him in the uses he will put it to, also the kind of a horse he feels will suit the conditions, and then he fixes, in his mind, the maximum amount he can afford to pay for such a horse, based on its usefulness, and looks for a willing seller having about the kind of a horse he wants.

Now, let us suppose the earnings of horses were regulated by law to only a fair return on their value. It would become necessary, under such circumstances, to seek a process which would show us what a

horse would be worth that could fill a particular need, at a regulated rate of earnings; the rate, in turn, being predicated on the value of the horse. This would reduce our stock farmer to a condition of mental coma, as it would introduce economic problems that are outside the domain of his practical experience, and he would probably have to seek the advice of a specialist.

Let us suppose that one of our modern, up-to-date utility commissions, with its engineering staff, were called in to help out, and suppose that it should proceed as we proceed to-day in the valuation of private property devoted to public use. First of all, it would probably take off the horse's shoes and weigh them, and compute the market cost of replacing them; then it would calculate the quantity of glue in the hoofs; get the measurement of the hide, and compute the fertilizer, estimate the grease, and value all the by-products at prices at which they could be purchased in the open market, and after all of this was done, it would total up the cost of reproducing the "physical property," so-called, and then perhaps suddenly discover that it had now only arrived at the cost of replacing a dead horse.

The problem would then be to find the added cost of producing a live horse, over and above the cost of a dead horse, and here the commission is in difficulty. The suggestion would occur to it, of course, that the hypothetical dead horse which it had just estimated, might be compared with the live horse which it is valuing, and the difference in cost might be called "going value," but this would not look very sensible. First of all, it would have to assume the cost of a live horse, which is assuming one of the results that are being sought.

Another method, following along the lines of the reproduction method, would be to give the carcass oxygen treatment, and, if possible, animate it into a live horse, which, after forced feeding and stimulants for a few days, might be able to do some work and earn certain revenue. The cost of all this biological proceeding might be compared, in the meantime, with the earning power of the live horse so as to arrive at "going cost," and be added to the carcass estimate. Some of the commissions would prefer to go back and see what it would cost to raise a horse from a colt, keeping track of the cost of feed, pasture, and care, crediting the horse with the work performed, and thus arrive at the net cost of the full-grown horse. Others would add the early deficits in earnings of the colt to the carcass value of the present dead horse, for

which they have completed estimates, and arrive at the net cost of a live horse in that way. Most engineers, new to appraisal work, would jump at the difference in cost between the dead and the live animal, but try to conceal the fact that they have guessed it under a mass of verbiage, which, when analyzed, is found to be evasive and meaningless. Once having arrived, by hook or crook, at the cost of a breathing working horse, most of our appraisal authorities stop, quite exhausted with such strenuous endeavor in these new fields of inquiry.

Now the difficulty of finding the going cost of a live horse, over and above the carcass cost, may seem far-fetched and not properly comparable with other kinds of property, but is it so far-fetched after all? What is it that goes into an incongruous mass of stone, brick, iron, and machinery that makes it a harmonious, useful, operating whole? Is it not brains, thought, patience, perseverance, foresight, ability, human energy, confidence, and wisdom? And these are but attributes of life; the characteristics of live things over and above dead things. When we make a property live, therefore, for useful purpose, we put something of the Divine human into it, which is little short of miraculous, and the operation of measuring this in terms of cost is necessarily a difficult and delicate task to which we must give careful thought, not only to the physical task of bringing a property to life, but to the psychological and ethical task of making it live usefully.

The stockman, however, might properly want to know what kind of a horse it was, after the appraiser had got it alive. Should it be classified as a race-horse, a carriage-horse, a cart-horse, or only just a jackass—and it might make a good deal of difference in earning power, as well as value, whether it were the first or the last?

Courts and utility commissions do not always disclose their mental processes, and, so far, we find on the records but little reasoning along the broader business lines which affect and surround the question as to whether the given utility is a race-horse or a jackass. Engineers, especially, are quite content if they can only get at the cost of a breathing, living horse, but it is pretty evident that this is an important question, and should be given a good deal more consideration in the future than it has had in the past.

Under the restricted methods of procedure, in which purely cost methods have such predominance, some utility properties have undoubtedly been undervalued, others must have been overvalued, and

unless we can come to appreciate the fact that surrounding conditions, good judgment, and skillful engineering tell in the value of a property, we shall not get away from this danger.

Now, the Courts and commissions being charged with the responsibility of determining values, which, in part at least, are dependent on rates, and at the same time of establishing rates which are a fair return on the value of the property, are under the most insidious temptation to lessen property values without appearing to do so, and without even intending to do so. This is due, in large part, to the unfamiliarity of the Courts and commissions with the business considerations which control the investment of capital and its expectation of profit, and also to the pressure of the public clamor as the buyer of service. Where appraisal authorities have yielded to these temptations, and particularly where they have failed to give due consideration to all the surrounding conditions outside of the cost evidence which go to make up value, they have, in some cases at least, placed the racehorse on a level with the jackass, and perhaps at times elevated the jackass to a dignity to which it was not entitled.

As has been said before, where a property is serving a real need in a community that is growing normally, and where its installation and management are without serious errors of judgment, the value of the property cannot be less than the cost of reproducing it in a manner that is humanly possible, less its depreciation. Ordinarily, it is worth more, and usually it would be considered poor financial judgment to sell a well-designed and well-established property in a growing town for the bare cost to reproduce it, were it not for the power of the Courts and the commissions to restrict value through the establishment of rates.

This brings us to the consideration of the economic law that when value depends on rates, rates must be such as to attract capital into the utility field or there will be no value commensurate with the necessary service; yet it is to be doubted if any actual rates so far established are of themselves high enough to account for the fact that capital is apparently continuing to move into certain kinds of utilities, especially into some of the municipal utilities. What are in reality the main inviting causes here may be summarized, as follows:

First.—The belief that the fundamental law of this country will protect property devoted to public use from confiscation.

Second.—The belief that legal supervision by non-partisan commissions will decrease the annoyance such investments have been put to in the past, and make the capital involved more secure.

Third.—The demonstrated fact that earnings from public utility investments do not fluctuate so greatly in financial depressions as do some other forms of investment.

Fourth.—The fact that the demand for the service will usually grow or can be encouraged to grow at a faster rate than the increase in population.

Fifth.—The probability, or at least the hope, that the value of the property in a public utility will grow with the community, irrespective of the actual investment in money.

Sixth.—The obvious intention of the Courts and commissions to treat such property fairly in the matter of reasonable rates.

So long as capital finds these conditions satisfactory, it will flow into the utility field in a selective way, but should these fundamental conditions be seriously altered or much changed for the worse, capital will grow timid, and will gradually withdraw.

In the case of privately owned municipal water supplies, for instance, the consumer public has, in the past, greatly overestimated the profits and underestimated the necessary value of the property required in the service, and, as a result, has so harassed such utilities that capital for many years has not only declined to enter the field, but has sought every opportunity to withdraw from it, even at a sacrifice. A further important instance illustrating this timidity of capital is noted at present in the steam railway field, where the adequacy of the present rates has come of late to be seriously questioned, and, as a result, capital has been less willing to enter the field during the last few years, with consequent higher cost to the railroads for money.

In reasoning from cost to value in public utilities, it is desirable to recognize that capital has properly treated the public, not only by good service, but by that further attention which wins and retains their good will, not that this of itself is an element of value, but it undoubtedly confirms and strengthens other elements of value.

On the other hand, we must take into consideration the fundamental treatment of capital by the public. If this is to be hostile and without intelligence, then values of all kinds will be lessened, and the

service will be ultimately destroyed. If it is to be scientific and just, then values will be maintained, and the service can be made efficient.

Now, the public is vitally and directly interested in the maintenance of values, just as capital is interested in having the public's good will, for without values we cannot have the use of capital, and without the use of capital we cannot have the reasonable service at fair rates, and we need and want the service.

In reasoning from cost and other evidence to value, however, there must be found some way to reward sound judgment, skillful engineering, and economical management, producing good service. This, none of the present utility laws as interpreted by the commissions, does; in fact, the present utility scheme of regulation, as now administered, distinctly puts a premium on poor or indifferent management, and takes away the incentive for economy. The next great problem in utility regulation will be to find ways of overcoming this defect.

In the meantime, there is no simpler way of recognizing good investments and careful management, where they exist, than by recognizing their effect in increased plant values, and this should be a part of the final reasoning in every valuation, just as much as indifferent judgment, absence of good engineering, and lack of economy should be similarly dealt with in the final summation.

It will always be very helpful if the maximum and minimum limitations to value be one of the matters to be reviewed before finally determining value, and, for this purpose, it is desirable, in the interests of the public, to reason out what would be the results of natural and economic conditions that would exist under a free competition that it is not wise actually to permit, and is not, in fact, intended to be permitted under our utility laws as they are now framed.

The average buyer in the open market always has his maximum price in mind, just as the seller has his minimum price, all of which is helpful in arriving at an exchange value. Helpful reasoning can be introduced along these lines in the final summation of public utility values. For instance, it would not be wise, on the one hand, to reward good judgment and skillful engineering in a property by fixing a value well above that which in an open and competitive condition would excite (if it were possible) the increased competition of a similar kind of supply or service, or the construction of a rival or duplicate property; nor, on the other hand, could we penalize dishonest financiering

and thoughtless construction by reducing values below the point where any service would be ultimately impossible, and the public finally be made to suffer.

Reasoning from the cost and other evidence to value, therefore, is a financial as well as a judicial and ethical problem, and if we would here do justice to the subject we must imitate the methods and habits of thought of the honest but alert business mind. When this economic study is followed through, it is striking to note how identical at every point are the common interests of capital and the public interest.

Conclusion.

There is probably no problem presented to the American public at the present time which is so difficult and complex as that of valuing the public utilities of this country. The value of these utilities is constantly fluctuating. It is dependent on many complex surroundings, and involves many difficult and delicate questions. To determine lines of evidence which will show the value of these properties in a way which the higher Courts have indicated, often involves the engineer, the economist, and the Court, in a complex hypothetical proceeding, which is only rescued from being absurd by being applied by competent and fair-minded men, with long practical experience behind them. The foundation for all this work undoubtedly rests in the law and its interpretation by the Courts, and the superstructure only is the field of the engineer and economist. Let us, therefore, as prudent men and experienced engineers be careful that we do not foolishly build on false premises and produce results which are "confusion worse confounded."

Once having founded ourselves properly as to principles, but one other great problem remains, that of holding to the judicial attitude. An entire paper might profitably be written on this subject alone. The engineer in appraisal work, to be successful, must keep himself unbiased and unprejudiced. At times he must resist the popular clamor for low, unjust, and unfair valuations, and at times he must resist the temptation to become the willing tool of powerful interests.

The preliminary bias in approaching public utility valuation has a great deal to do with progress in solving its difficult questions. Roughly, there are six classes of minds that ordinarily approach the problem of public utility valuation:

First.—Minds which are only familiar, by sentimental interest, with the rights of the public, and care little or nothing about learning about the conservation of property.

Second.—Minds which are fully familiar with the rights of the public, but are also open-minded and desire to learn about the conservation of property.

Third.—Minds which are, by training and environment, only familiar with the rights of property, and are not open-minded about learning anything about the rights of the public.

Fourth.—Minds which, by training and environment, are only familiar with the rights of property, but would also like to be unbiased and know more about the rights of the public.

Fifth.—Unbiased minds which are interested in just relations between the public and private property interests, but have not fully analyzed both viewpoints or had experience with both situations.

Sixth.—Minds which are naturally unbiased and are interested in and have mastered the just relations between the public and private property interests.

Classes 1 to 3 are worse than useless as appraisers, and, as writers, serve only to obscure and befog the problem of the just relations between the public and private property. They, too, often produce heat when there should be light. They are usually hopeless, and should not be entrusted with judicial functions in utility valuations.

Classes 2 and 4 may or may not develop into Class 5 or 6, depending on their inherent fairness and opportunity to study the opposing side of the question. Usually, they do not get enough opportunity to study the reverse side of the question until their opinions are too firmly fixed to be altered.

Class 5 may develop into Class 6 if opportunities come for sufficient experience and study on both sides of the question. They have analytical minds and judicial natures in the making.

Class 6 can only come from an unbiased and analytical mind that has had ample experience in representing both sides of the question.

To produce good results it is necessary, in appraisal work, to have practical experience in considerable amount, not always representing one side, but alternately representing both conflicting interests, in

order to appreciate fully the varied points of view which can be brought to this difficult matter.

Cross examinations in court, conferences with able attorneys, familiarity with the views of Courts and commissions, arguments with opposing valuators, experience on various kinds of appraisals: these all develop the practical, fair, and unbiased appraiser.

Nothing is so illuminating as to find oneself demonstrating value from two opposing viewpoints in two consecutive appraisals. A few experiences of that kind give one confidence in one's own sense of justice.

There is one golden rule for the engineering appraiser in valuation work:

Always value a property so that you would be satisfied with your valuation were you appointed by the other side at interest, and so that you will be satisfied with it ten years hence, as well as satisfied with it next month, if you actually find yourself on the other side of the issue in some other case.

APPENDIX.

Legal Decisions.

If the opinions advanced in this paper are well founded, then engineers who propose to fit themselves for valuation work should by all means make a careful study of the opinions of the Courts. What is greatly needed is a book, compiling in full, without partiality, the decisions and opinions of the Courts in valuation cases, all of which should be accompanied by a topical index. Probably this will be produced and published at some early date, as the importance of the subject now urgently requires that it be done.

In the meantime, a list of the more important decisions, especially those of the Supreme Court, is appended to this paper for immediate reference. The list may be profitably extended, but it is believed that most of the leading cases are included:

Ames *vs.* Union Pacific Ry., 64 Fed., 177; Digest, 2, 13, 26, 34, 38; Abstract, 48 to 50.

City of Bristol *vs.* The Bristol Water-Works Co., 23 R. I., 278, 49; Atl., 974.

Brymer *vs.* Butler, Pa., Water Co., 179 Pa., 250.

The Brunswick and Topsham Water District (Me.) *vs.* The Maine Water Co., 99 Maine, 371.

Baker *vs.* Gertside, 86 Pa., 498.

Chicago Railroads *vs.* Day C. C., 35 Fed., 866.

Railroads *vs.* State of Minnesota, 134 U. S., 418-456.

The Cedar Rapids Water Co. *vs.* City of Cedar Rapids, 91 Northwestern, 1051.

The Cedar Rapids Gas Light Co. *vs.* City of Cedar Rapids, 120 N. W., 966.

Cotting *vs.* Kansas City Stock Yards Co., 183 U. S., 79.

Contra Costa Water Co. *vs.* City of Oakland, Cal., 113 Pac., 668.

The Consolidated Gas Co. *vs.* City of New York, 157 Fed., 849-855.

Covington Gas Co. *vs.* City of Covington, Ky., 22 Ky., L. R., 796.

The Des Moines Water Co. *vs.* City of Des Moines, 192 Fed., 193.

The Galena Water Co. *vs.* City of Galena, 87 Pac., 735.

The Gloucester Water Co. *vs.* City of Gloucester, Mass., 60 M. E., 977.

The City of Janesville, Wis., *vs.* Janesville Water Co., R. R. Comm., Vol. 6, 628.

The Kennebec Water District *vs.* Waterville Water Co., 97 Maine, 185.

The City of Knoxville, Tenn., *vs.* The Knoxville Water Co., 212 U. S., 1.

Little Falls Electric and Water Co., 102 Fed., 663.

Monongahela Navigation Co. *vs.* U. S., 148 U. S., 312.

Munn *vs.* Ill., 94 U. S., 113, 133.
National Water-Works Co. *vs.* Kansas City, 62 Fed., 853.
Newburyport Water Co. *vs.* City of Newburyport, Mass., 168 Mass., 541; 47 N. E., 533.
The Norwich Gas and Electric Co. *vs.* City of Norwich.
The City of Omaha *vs.* The Omaha Water Co., 30 Sup. Ct. Rep., 615.
Peck *vs.* Chicago R. R., 94 U. S., 164; 24 L. Ed., 97.
The Pioneer Tel. and Tel. Co. *vs.* Westenhaver.
Queensborough Gas and Elec. Co. *vs.* Pub. Ser. Com., N. Y.
Redlands Water Co. *vs.* City of Redlands, Cal., 121 Cal., 365.
Stanislaus County *vs.* City of San Joaquin and Kings River Co., 192 U. S., 201.
San Diego Water Co. *vs.* City of San Diego, 118 Cal., 556.
San Diego Land and Town Co. *vs.* Jasper, 110 Fed., 702.
San Diego Land and Town Co. *vs.* Jasper, 189 U. S., 439.
San Diego Land and Town Co. *vs.* National City, 174 U. S., 757.
Slocum *vs.* City of North Platte, Nebr., 192 Fed., 252.
Smyth *vs.* Ames, 169 U. S., 466.
Spring Valley Water Co. *vs.* The City of San Francisco, Cal., 124 Fed., 574.
Spring Valley Water Co. *vs.* The City of San Francisco, Cal., 192 Fed., 137.
Spring Valley Water Co. *vs.* Schlotte, 110 U. S., 347; Sup. Ct., 4851.
Trust Co. of America *vs.* City of Rhinelander, Wis., 182 Fed., 64.
C. H. Vanner *vs.* Urbana W. W. Co., 174 Fed., 348.
Washington Gas Light Co. *vs.* District of Columbia, 161 U. S., 316.
Willcox *vs.* Consolidated Gas, 212 U. S., 19-54.
Wilkesbarre *vs.* Spring Brook Water Co., 4 Lack., Legal News, 567, 380.
Western Union Tel. Co., *vs.* Myatt C. C., 98 Fed., 335-342, 354.
Bothwell *vs.* Consumers Co., 13 Idaho, 568, 9e Pac., 533; also 24 L. R. A. (U. S.), 485.
Minnesota Rate Cases, 230 U. S., 352.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

THE VALUATION OF PUBLIC UTILITY PROPERTY.

By J. H. Gandolfo, Assoc. M. Am. Soc. C. E.

To be Presented November 18th, 1914.

Synopsis.

The primary object of this paper is to show that, in any valuation or appraisal that is to be made for purposes of rate-making or security issues, the proper figure to be used is the actual cost to date of the work in question; provided, of course, that there has not been extravagance, fraud, or gross mismanagement in the origin or development of the enterprise. At the same time, it is also shown that, although this value is a basic figure, it is not necessarily the only and final one to be used for any and every purpose for which a valuation may be undertaken. Reproduction or replacement cost, cost of reproduction less depreciation, etc., all have their proper place, and should be used under the proper conditions.

In order to show this, it has been necessary to go back to the fundamental beginnings of business, as exemplified in the private business, and trace the development of the private corporation and the public utility corporation from this origin, at the same time showing the similarity and dissimilarity between these three classes of organizations. With this as a basis, it is shown how the same principles can and should be applied in the valuation of public utility property as would be used in that of a private individual.

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

This has been done under the three headings: I.—The Private Business; II.—The Private Corporation, and III.—The Public Utility Corporation. The last is again subdivided, and different phases of the subject are more or less fully treated, applying the principles as deduced from the other two divisions.

In investigating the public utility, it is also shown briefly why this class of corporation should be subjected to regulation by the State, this regulation being a necessary result of the circumstances attendant on the development of these corporations from the private business and private corporation.

Inasmuch as the final test of a physical valuation is its ability to stand a review by the Courts of last resort, the decisions of such Courts are referred to in the following pages wherever it has been thought necessary to show the trend of judicial opinion; also, it has been found advisable to quote at times from some decisions, not only for purposes of clearness, but for purposes of criticism.

In conclusion, the writer states that the actual cost to date is a figure equable to the investor, the promoter, the manager, and the public at large. The real object of a valuation is to obtain a figure equable to all parties interested in the particular case under consideration, and every case must be decided on its own merits, and with due regard to the conditions and circumstances immediately surrounding it.

Introduction.

In any work of valuation or appraisal, no matter for what purpose, there are of necessity many perplexing questions that are bound to arise, and their solution will tax to the utmost the experience and resourcefulness of the investigators. On the other hand, there are also fundamental principles governing such work, which, if studied and analyzed, will serve to elucidate many matters which are subjects of controversy at the present time.

In order to arrive at such fundamental principles and obtain a firm basis on which to found axioms for the valuation of the property of public utility corporations, it is necessary to investigate the development of this class of business from its beginnings, and to study it from economic as well as from financial standpoints. To attempt to unravel successfully the so-called mysteries of valuation and ap-

praisal, without such an investigation and without comprehending such first principles, is an absolute impossibility.

One of the principal reasons for so much confusion in regard to certain phases of the valuation of public utility property is that all investigators or appraisers fail to understand clearly wherein a public utility corporation possesses the same attributes as a private business, and, on the other hand, wherein it differs entirely. Therefore, it is necessary to show where the three classes of concerns, (1) the Private Business; (2) the Private Corporation; and (3) the Public Utility Corporation, are similar, and wherein they are radically and entirely dissimilar. In order to do this, and to make matters perfectly clear, it will be necessary to set forth some elementary facts relating to business in general, which perhaps are well understood when attention is called to them, but are forgotten or ignored by discoursers on these subjects.

In the following pages, it must not be supposed that the writer attempts to follow out in full detail all the intricacies of promotion, preliminary investigation, organization, underwriting, financing, or the dozen and one other steps that go to make up the history of any large business enterprise carried to a successful completion. On the contrary, the attempt has been made to describe briefly and in a clear, concise manner the principles that underlie such an undertaking, in so far as they are applicable to the valuation of public utilities. No reference will be made to any company organized simply for the purpose of placing stocks, without the intention of carrying the enterprise to a successful conclusion. It is assumed for the purpose of this discussion that the company is properly organized, is well managed, and that the intention is to return dividends to the investors. It is further assumed that, as far as ordinary business is concerned, there is free and unrestricted competition, and that there is no artificial control by combinations or trusts. Monopoly control is not considered, except in connection with the public service corporation. Such combinations in private business introduce elements into the investigation that are not germane to the scope of this paper.

I.—The Private Business.

Let it be assumed that an individual wishes to engage in a private manufacturing business of some kind, or that he is already engaged

in such. Aside from the transactions incident to trade requirements, the only direct financial dealings that such a concern would have with even a portion of the general public, in which any favors are asked, is the possible necessity of borrowing money from banks. If banks loan money on the concern's notes, such loans are secured by the value of the plant, by the value of the raw or finished material on hand or in progress of manufacture, or by bills receivable, all of which are tangible assets. Other risk of direct loss is taken by those parties selling to the concern raw or finished material on time payments. The notes are soon paid back, the same process being continued over and over again as the necessity arises. Therefore, the risk taken by the general public is practically nil, as it is taken only by those directly interested in the banks from which funds are borrowed, and who, acting through their boards of directors, have taken the chance of the concern not being able to meet its maturing obligations through some unforeseen accident, such as a falling market, financial panic, or similar causes.

In addition, in any dealings with such a concern, a creditor is further secured by the fact that the owner is personally responsible and that all his personal assets are liable as security in case other means fail; in strong contrast to a stock company, in which each stockholder is only liable for the amount of his stock, no matter what mismanagement may have developed or what debts may have been contracted.

If the concern is a co-partnership, the same conditions as those described are applicable, only in this case the risk is apt to be more extended, as there are two or more partners, and, in addition to banks, personal friends of the various partners are more likely to become involved in a failure, thus indirectly leading to a broader dissemination of the results.

If such a concern wished to extend its plant, this would be accomplished in one of two ways: (*a*) the owner would do with less personal returns and thus accumulate a surplus to be used for additions and improvements; or (*b*) he would raise the necessary funds from his banks, with property or other tangible assets as security, or from his personal friends, these loans to be paid back from the profits of the additional business before any benefit would be expected by the owner.

As to the returns to be anticipated from the business, this is simply a question of the law of supply and demand, modified by the ignorance, apathy, patience, desire, or necessity of the community. If the service is not satisfactory, or the grade of goods is not up to such a standard as the purchaser thinks is essential, as there is free competition, he can go elsewhere and obtain what he thinks is satisfactory. If too high a return is demanded, then, on account of the prospects of large profits, still other manufacturers will be induced to enter the field, engender more competition, and so reduce prices. One exception to this would be where some patented or secret process was in use, in which case the only check on the returns to the owner would be the desire or necessity of the public for the commodity, and its ability to pay for it.

As to the physical value of such a business, the owner would naturally carry the actual cost of the plant to date on the credit side of his balance sheet, minus such percentages as he had charged off for depreciation and obsolescence. If a fund for depreciation and obsolescence had been actually placed in trust for the renewal of the plant, it would be a tangible asset of the concern. If not, the owner would have to expect to renew the plant out of his own capital when the time came, just as he had originally built it out of his own funds; or else go out of business at the end of some period with his capital theoretically all returned, plus the amounts that the plant had earned, over and above the depreciation charges, during the years of its operation. It is not to be expected that an owner of such a plant would, under any circumstances, carry its present-day or replacement cost on his books, as such a quantity would have no place on his balance sheet, and, furthermore, would be a constantly varying figure. Neither would such a figure enter into the calculation of profits. Such profits would be based on the actual cost to date, not on any replacement value or present-day value.

If the owner of this business wished to sell it, or if some other party wished to purchase such a plant, the owner would have a perfect right to ask a price such as it would now take to replace his plant, less depreciation, or to erect a new one to produce the same results, which price might be greater or less than the original cost of the original plant, with all its additions and improvements to date. In addition to this purely physical valuation founded on present-day

values, the owner would also ask an additional sum to cover the fact that the business is a "going concern", that is to say, that it is organized, that it has customers, that it has an outlet for its products, and that it possesses the good will of its patrons. What such a figure would be, it is impossible even to estimate. It would depend on such circumstances as (1) the owner's desire to sell; (2) the buyer's desire to own such a plant, modified to a large degree by his ability to build a competing plant if not able to purchase; (3) by the state of the market for the commodity produced, whether rising or falling; (4) by general financial conditions. It is impossible to mention all the many causes, personal, economic, and financial, that might influence such a sale value one way or another.

If, instead of trying to buy the original plant, another party should build a new one and start operations, this new manufacturer would have had to consider (1) the possibly higher cost of the new plant, due to higher material and labor costs; (2) the necessity of building up a new business; (3) possible lessened income due to more competition; (4) lessened income in the early period of development due to faulty organization; (5) necessity of marketing the product; (6) failure due to over-production, etc. All these and many other conditions and circumstances would have to be carefully weighed and investigated before the enterprise was started; but, would the owner of the original plant make any changes in his investment costs? Would he increase the book cost of his plant, because some one else had built a more expensive plant to accomplish the same result? He would simply rest secure in the knowledge that he possessed this advantage over his rival. The new plant, perhaps costing more, must compete with the handicap of higher investment costs, modified perhaps to a greater or lesser degree by more efficient machinery and arrangements than those possessed by the old plant.

If the owner of a private business wishes to retire, there is no restraint to prevent him from so doing. At any time and at a moment's notice, provided he is solvent and has no outstanding contracts that must be fulfilled, he can close his doors, say "I am done and finished", and no one can compel him to continue in business.

The private concern never asks any favors of the municipality or of the State, such as the right to use the streets for car tracks, string-

ing wires, laying pipes, or other uses, or for the building of a railroad or the development of a water power. Nor can it invoke the right of the law of eminent domain to further its own affairs. It is subject to the same laws, rules, and conditions as the entire body politic, and thus, having accepted no special favors from the State, the private concern is not, and cannot be, required to return any special favors to the State.

Such, in brief, is an outline of a simple private business. It must not be supposed, however, that all details are covered or that all incidents which might arise have been mentioned. Any business is susceptible of endless modifications and extensions, and is highly sensitive to all those changes and developments which are constantly taking place in the business world. The outline is given as an exposé of the essential principles of such an organization. Its very fundamental simplicity is to be kept in mind, in connection with the investigation of both the private corporation and the public service corporation.

II.—The Private Corporation.

With the advent of the great stock company, with its large capitalization, its stocks and bonds, and its hundreds and even thousands of stockholders, we come to a new era in the business world, and here begins that intimate relation between the promoters, owners, managers (or whatever other name may be applied to the controlling interests of such a concern), and the general public at large. This relationship passes through all stages of development until the condition is reached where the concern becomes a public utility corporation, managed for and in the best interests of the people at large, who may now have no direct interest in the securities of the company, and yet, at the same time, may control its destinies through commissions and State legislatures.

All private corporations may be grouped in two classes, as follows:

(*A*). The corporations generally known as "close corporations," in which all outstanding securities are held by a few individuals, generally close business associates; and

(*B*). The corporations which, on their organization, offer to the general public stock or bonds, or both, and ask the public to purchase them and become part owners in the enterprise.

In regard to those corporations coming under (*A*), there are three reasons for organizing such a company:

(1) To provide against the disruption of the organization on the death of any prominent member. When a death occurs among the owners of a private business, it generally means the closing and winding up of the firm's affairs. On the death of any one holding stock in a corporation, however, the business is continued as before, under the direction of the board of directors. The securities held by the deceased simply pass into other hands.

(2) To limit the liabilities and responsibilities of those who hold stock in the corporation. As previously stated, the owner of a private business is liable to the full extent of his property, but the holder of stock is liable only to the extent of the amount of stock held by him.

(3) To enable an individual who is a bankrupt, to continue or engage in business, under the name of "manager" or "proprietor," the stock of such a company being held by a few of the "manager's" friends.

The corporations that come under (*A*), as long as they remain in this class, are practically private concerns, and no special attention need be given to them. On the other hand, however, the line between (*A*) and (*B*) is not at all clearly defined, and a company that is classed under (*A*) may at any time come into the other class by offering its securities to the public.

The primary object of organizing a large private company, such as classed under (*B*), is for the purpose of obtaining funds with which to carry out an enterprise of such magnitude that the money cannot as a rule be raised among a few individuals. Such an organization also enables an individual to take an interest in the company, by the purchase of a small amount of securities, he knowing that the amount actually invested by him is the only sum he risks, and that all his assets are not liable. The small investor can thus enter into and obtain the benefits of a large business, whereas if limited to the co-partnership arrangement, he would be unable to do so. In addition, such a company makes it possible for a few small investors, by thus pooling their capital, to engage in a business which otherwise would be controlled only by men of great wealth and financial standing in the community.

After the work of preliminary investigation and organization has been completed, such a company begins its public career by applying to the State for a charter of incorporation, and sets forth in such charter in what ways it proposes to exercise its activities. The promoters, then, on its incorporation, ask the general public to become owners or partners in the enterprise by the purchase of its securities. As it is impossible for all such stockholders to take an every-day active management in the company, such management is vested in a board of direction, the members of which are elected by the stockholders and are answerable to both the stock and bondholders.

The actual cash outlay for the enterprise, including all preliminary work, construction costs, and working capital must be raised by the sale of securities. In order to obtain this capital it is at present the general custom to offer the bonds of the company at a discount, not so much for the purpose of increasing the rate of interest on the investment, which is what such discount really amounts to, but simply to play on the psychological element of the human mind, which wishes to believe that it is getting something for nothing. Where an entire issue of bonds is underwritten by a banking house, or a syndicate composed of several such houses, part of such discount may cover the brokerage fee for handling and placing the securities and guaranteeing the funds when actually needed by the corporation. For example, if an issue of bonds is taken by a syndicate at 90, the syndicate takes the responsibility of placing them among the general public at some figure in advance of this and making the difference as its fee for the work. Such underwriting is more apt to be done with the securities of a public utility than with those of a private company. In addition to this discount on the bonds, a percentage of such purchase price, in stock of the company, is often given to each buyer of the bonds as a bonus, a part or all of which the syndicate may retain as part of its fee.

The promoters and organizers of the enterprise, in order to be remunerated for their work, also expect to be paid with a large block of stock, or with part cash and part stock of the company. In addition, as these organizers as a rule also wish to keep control of the company, enough stock must be issued and held by them so that a majority vote of the said stock will remain in their hands. Frequently, it happens that if a few individuals subscribe to a large percentage

of the issue of bonds, these men will insist on keeping control of the company, and so much stock is issued to them to insure such control. It is thus seen that the average corporation necessarily starts out with a certain amount of over-capitalization, or "water" in its securities, which it is impossible to prevent under present-day laws and conditions. This necessary over-capitalization, therefore, consists of the following:

(1) Promoters' remuneration in stock and cash;
(2) Discount on bonds;
(3) Stock distributed with the bonds as a bonus;
(4) Stock issued to keep control of the company.

On account of the way in which the business of the company is managed (by the board of direction), and because the company is controlled as described by stock issued for the purpose, the small investor, or "minority stockholder" as he is generally called, has very little voice in the real affairs of the concern. The Courts have ruled time and time again, when matters have been taken before them by minority stockholders, that, as a general proposition, in the absence of fraud or special circumstances, it is a question of "the greatest good for the greatest number."

More important, however—and of most consequence to the community at large—is the fact that the security holders of a large corporation are able to go to the banks and borrow cash, giving as collateral these stocks and bonds. Even the concern itself is able to borrow money from the same source, on the stock and bonds that it may have in its treasury. Thus stockholders of the banks and depositors who really may wish to have nothing whatever to do with some particular corporation, are brought into the matter entirely without their knowledge or consent. The financial world is filled with cases wherein banks have loaned to their full capacity on securities on which, in times of financial stress, they have been unable to realize, and have thus been unable to meet the demands of their depositors, although the securities in themselves were good and the concerns behind them perfectly solvent.

The stock company is thus seen to vary greatly from the private business, particularly in the following essential principles:

(1) The real "owners," or those who have actually supplied the capital, may have practically nothing to say about the management of the company, and have no control over their own investment.

(2) The company may have outstanding more or less securities which, having been issued to cover what may be termed "intangible elements," have nothing behind them in the way of tangible assets. When such securities are sold by the original holders, and pass into the hands of the public, there is nothing to distinguish them from those that are supported by tangible assets.

(3) These intangible securities, as well as those supported by tangible assets, may be used, through the medium of the banks, to borrow money from the general public.

(4) Returns in the form of dividends must be secured on a larger amount than the actual capital invested in the actual tangible business, as all securities issued are expected to bring in returns to their owners.

Aside from these matters, and as far as the actual conduct of the business itself goes, the private corporation does not differ materially from the private business, except in details which are not material for this discussion.

It is for reasons such as those briefly outlined that the State exercises control over all private corporations, and justly subjects them to rules and regulations that will protect, not only the public at large, but also those directly interested in the company. Some States exercise such control with a firm, and at the same time just, regard for the rights of all concerned, and others do so in a careless and haphazard manner that leads to fraud and corruption of every description. However administered, such control by the State is an absolute necessity. In other words, the State is beginning that unfortunately necessary paternal supervision over private business, which, later, finds its greatest expression in the direct control of the public utility corporation by the State.

III.—The Public Utility Corporation.

1.—General.—To-day we use the terms, public utility corporation, public service corporation, or quasi-public corporation, without a very distinct idea as to just what is included or should be included by these terms in the way of corporations. With our rapid development, the purely private business of to-day may become the public

utility of to-morrow. Almost everything now classed as a public utility was unknown a short hundred years ago. In ancient and medieval times, great cities existed and flourished, there were no railroads, and steam was unknown. To-day, however, the railroads stand at the head of our public utilities, and how could a modern city exist without them? How long will it be, therefore, before other lines of business endeavor now considered purely private matters will be classed as "public utilities?" As time goes on, more and more concerns, with more and more diversity of products or lines of endeavor, are being brought into this category. Therefore, what is a public utility, and how can it be defined and distinguished?

A public utility corporation, or a public service corporation, may be defined as a private company which exercises its functions in a direction that is of vital importance to the members of the community reached by its activities. Webster says:

"Private corporations, including all others of a civil nature, as ordinary business corporations and those corporations such as railroad companies, lighting companies, water companies, etc., organized or chartered to follow a public calling or to render service more or less essential to the general public convenience or safety, and now often called public service corporations or sometimes quasi-public corporations."

The great distinguishing characteristic of the public utility corporation, which separates it from the private company or private business, is, that it is organized with the idea of working to a certain extent in direct co-operation with the community—and by community the writer means either a village, a city, a State, or a Nation. Such a corporation asks certain definite concessions and grants from the State, as a preliminary to starting in business at all. For example, the railroad asks the right to cross or close highways; to take property from citizens by right of eminent domain (and, of course, for a just compensation); to build bridges across navigable rivers; to narrow the waterway of smaller streams, or even to change their course and direction by means of embankments and fills; the street railway, the water company, the gas company, the electric light and power company, all ask the right to use the public streets to conduct their business; the power development company asks the right to dam rivers and use the water for private gain. Of transcendental im-

portance, however, both to the corporation itself and to the community at large, is that of necessity this class of corporation is a monopoly; if not *de jure,* at least *de facto.*

In return for all these special privileges granted to it by the State, the company promises necessary or useful service of some kind to the citizen. It is the abuse of such privileges on the part of the corporation and, on the other hand, onerous conditions imposed by States on such companies, that have brought about the necessity of just regulation and control of them by the State. That such regulation is equable, few will question at the present time; but how it is to be accomplished, and on what basis, is another matter.

As a basis for the control of any public utility, it is necessary to know the cost, present value, or fair value, of all the property, both tangible and intangible, that goes to make up the utility. Without such knowledge it is impossible to form any definite plans to regulate these companies.

It is in regard to such value that the first serious divergence of opinion occurs among appraisers, and this lack of unanimity exists, not only among engineers, but also among financiers and the judiciary. For example, in making a valuation, should actual cost to date, cost of reproduction new, or fair or market value, be used? Should such matters as depreciation, obsolescence, and inadequacy, be taken into consideration? Inasmuch as the rights and privileges of the company have been conferred directly by the State, should such intangible elements as going concern values or franchise values be considered?

In any valuation work that is to be subjected to judicial review (and practically every appraisal must sooner or later stand this test), it is necessary to give careful study and consideration to Court rulings on the subject, in order that the work may hold through such an ordeal. It must not be forgotten, however, that a Court is compelled to render a decision on the evidence as presented before it. If a case is presented in a different manner, supported by the proper evidence, the ruling of the Court is apt to be very different. The writer's experience in court has shown conclusively that an attorney, although he may have a good case, through lack of proper study and a thorough understanding of its principles, may present it in such shape as to leave the Court no alternative but to give an adverse decision in the matter. The entire subject of valuation and appraisal is still in its

infancy, and the records of the judiciary show that higher Courts have repeatedly reversed the decisions and rulings of lower ones. Therefore, too much dependence cannot be given to judicial precedent in matters relating to public utility valuation and control.

After having given careful study and thought to the matter, coupled with practical experience in this field and an investigation of commercial relations in general, it is the writer's opinion that actual cost to date is the logical and just figure to be used as a fundamental basis for public utility control. Although such actual cost should be used as a basis, it does not follow that this is the final figure that should be used for any and all purposes for which a valuation may be made. The writer does not agree with those who hold that the same ultimate figure should be used, no matter what the purpose of the valuation. The object of the valuation very properly should affect, not only the final figure, but possibly the method of conducting the examination as well.

2.—Valuation for Rates and Security Issues.—In any valuation for the purpose of rate-making, or for regulating the issuance of securities, actual cost to date is the final figure that should be used, provided there has not been fraud, incompetency, extravagance, or anything of a kindred nature in the development of the utility. Such cost should include:

(1) All preliminary work of developing and organizing the enterprise, including promoters' fees.

(2) Preliminary investigations and preliminary engineering work of all kinds.

(3) All final engineering work, including the preparation of final plans, supervision of construction work, etc.

(4) All construction work of whatever nature, up to the starting of the enterprise.

(5) All other overhead charges during construction, which include administration, organization, legal expenses, taxes, insurance, interest, etc.

(6) All additional work of new construction built since operation started.

(7) Where new work has replaced old, and the cost of this new work is greater than that of the old, the difference in cost between the old and the new must be included; but care must

be taken that maintenance is not by any chance classed as new work.

(8) All working capital.

The actual cost should not include:

(9) Anything in the way of excessive promoters' fees or profits, or excessive salaries during construction.

(10) Anything in the way of engineering or construction work that partakes of the nature of fraud, incompetency, or extravagance.

(11) Discount on bonds.

(12) So-called development expenses during the early stages of the operation of the enterprise.

(13) Any part of the development that is not actually used or useful in the operation of the utility for the public benefit.

(14) If new work has replaced old, such as a heavier bridge, or a new cut-off, and the cost of this new work is included in the valuation, under no circumstances must the cost of the now abandoned and useless work be included also.

Many of the most important legal decisions relating to valuation uphold the present or fair value, as the equable one to use for either of the above-mentioned purposes. In view of the general increase in construction costs, this practically amounts to cost of reproduction less depreciation. (See Ames *v.* U. P. Ry. Co., 64 Fed., 165; Smyth *v.* Ames, 169 U. S., 466; Willcox *et al. v.* Consolidated Gas Company, 212 U. S., 19; Cedar Rapids Gas Light Company *v.* Cedar Rapids, 223 U. S., 670.) The principal grounds on which these decisions are based, and on which the advocates of this system of physical valuation found their arguments, are as follows:

(1) Many of the older corporations, such as the railroads, were organized, and the utility built and operated, before State regulation in detail and public service commission control were thought of, and that, therefore, it is not now equable to deprive these companies of the increased value of the property.

(2) Also, in the case of these older utilities, it is almost impossible to get any idea of the actual cost of the property to date.

(3) The company is entitled to the benefit of any increase in the value of its property since construction, and if such increase is not

allowed, it amounts to confiscation of property within the meaning of the Fourteenth Amendment of the Constitution. Conversely, if the property has decreased in value, the company must stand this loss.

In the case of some of the older public utility companies, there are undoubtedly grounds for the contention that not to allow the increase in value which has occurred would perhaps amount to confiscation. On the other hand, such companies have had a long period of unregulated existence in which returns may have been received sufficiently in excess of what are now considered equable to the community to cover this matter. In order to reduce physical valuation to some standard basis, it may be necessary to ignore some such claims in the future. No change, however slight, can be made in our commercial and financial systems without working some injustice. In a change so potent as that of the regulation of these companies, it would be strange indeed if some unavoidable injustice was not done.

It is also to be remembered that all these old corporations received their rights, immunities, and special privileges directly from the State. It is a fundamental principle of the old English law, that no legislature can limit or restrict the actions of any succeeding legislature. Therefore, any such body can alter or modify the acts of any previous similar body, and can even revoke franchises or other special privileges. Such acts, however, on the part of a legislative body, are in their turn modified and controlled by decisions of the Supreme Court (which have always upheld the Fourteenth Amendment) that property cannot be confiscated, directly or indirectly, but can only be taken by due process of law. (See Stone and others *v.* Farmers' Loan and Trust Company, 116 U. S., 307.)

It must likewise be kept constantly in mind that the price of all material and of all labor entering into the construction of public utilities, has risen in value, with very few exceptions, since the older utilities were built, and, therefore, in spite of improved methods of construction, the present-day value is higher than the original cost. In the case of land, this has often increased in value three or fourfold, and sometimes, especially in the case of city property held by railroads, eight or tenfold. It is for this reason that all public utility companies wish the present-day value to be used as a basis for rate regulation or for the issuance of securities.

Although many decisions uphold present or "fair value" as the proper one to use for rate purposes, there are others that uphold actual cost to date as the just figure to be used. (See San Diego Water Company *v.* City of San Diego, 118 Cal., 556; 50 Pac., 633; Brymer *v.* Butler Water Company, 179 Pa., 231; 36 Atl., 249; Interstate Commerce Commission, in Advances in Rates, Western Case, 20 I. C. C. R., 307.)

In addition to these decisions, if some of those which uphold present and fair value are examined, places will be found which indicate that the Court is not at all sure of its stand. For example, in Smyth *v.* Ames, Justice Harlan said:

"And in order to ascertain that value, the original cost of construction, the amount expended in permanent improvements, the amount and market value of its bonds and stock, the present as compared with the original cost of construction * * * are all matters for consideration * * *."

In this decision the fact of original cost being an important element in an appraisal is admitted.

In Ames *v.* Union Pacific Railway Company, Justice Brewer said:

"Nevertheless, the amount of money that has gone into the railroad property—the actual investment, as expressed, theoretically, at least, by the amount of stocks and bonds—is not to be ignored, even though such sum is far in excess of the present value."

This opinion needs no comment.

In Willcox *v.* Consolidated Gas Company, Justice Peckham said:

"If the property, which legally enters into the consideration of the question of rates, has increased in value since it was acquired, the company is entitled to the benefit of such increase. This is, at any rate, the general rule. We do not say there may not possibly be an exception to it, where the property may have increased so enormously in value as to render a rate permitting a reasonable return upon such increased value unjust to the public."

Justice Peckham here lays stress on what he terms "the general rule," but the question naturally arises, What is this general rule, who made it, and why should it be used as a basis of a decision by the Supreme Court of the United States? The Justice further says, that if the value has greatly increased, it might be unjust to the public to base rates on such greatly increased value; but, if this

would be an injustice to the public, why would not a rate based on any increase in value be unjust? Who is to decide in such a case where to draw the line between such increase on which rates would be just and where they would be unjust?

Another argument against the use of this increase in value is that a public utility corporation does not go into business with any idea of speculating in its investment, any more than a private manufacturing concern does. The increase in value has not been caused by any direct efforts on the part of the company, and amounts to an "unearned increment" on which the public should not be required to pay rates.

As to the impossibility of obtaining the actual cost of a utility, this contention is also doubtless true in the case of some of the older concerns, but the writer thinks that the difficulties are greatly over-estimated in many cases. In any event, this is no excuse for putting all other utilities in the same category. If the actual cost to date is available, or if it can be obtained with reasonable efforts, to ignore this value and appraise the property on any other basis, such as reproduction cost, is to enter unnecessarily into the realms of speculation and surmise, which is so severely condemned by Mr. Justice Hughes in the Minnesota Rate Cases, in referring to land values (Simpson *et al. v.* Shepard; Same *v.* Kennedy; Same *v.* Shillaber, 230 U. S., 352).

Some few years ago the writer was chief assistant in an important investigation and appraisal of a large private industrial plant, which work was used in a suit in the United States Circuit Court involving a claim of $30 000 000. In this case the original cost of the plant was available, but it was necessary to examine carefully the actual property, and check conditions as they existed with the actual cost of the work. In addition, it was also necessary to follow back commercial conditions for the nine years previous to the appraisal, and discover what results would have been accomplished under such conditions. Of course, this was a long and tedious process, and absolute accuracy was essential on account of the legal aspects of the case. There was no reason, however, why these conditions could not have been traced back twenty or thirty years as well as nine; and, if the actual cost of the plant had not been available, it would have been perfectly feasible to appraise it at any period in the past (within a

reasonable time), using such prices and values as applied to that period. In this case, the present or fair value of the plant would have had no possible significance.

The actual cost to date represents the actual amount of capital invested in the enterprise; it is the amount on which the investors expect returns, and, if the enterprise is a success, on which they should receive dividends. This figure is also a constant quantity, it only being necessary to correct it for additions made from time to time; whereas, the present value (or value obtained by any other method) is a constantly changing quantity, it being necessary to alter it as conditions and prices fluctuate.

In order to demonstrate one phase of this problem, let it be assumed that the cost of reproducing a utility would now be less than when the plant was placed in operation. If the State or the Court should say to the corporation, "You must reduce your capital under the conditions as they now exist," the writer fails to see why this is not confiscation of property within the meaning of the Fourteenth Amendment. It is not just thus to wipe out invested capital, as Justice Brewer pointed out in Ames *v.* U. P. Ry. Co., 64 Fed., 165.

One of the arguments against using the actual cost under such circumstances is the claim that there are many utilities, especially railroads, which could not charge a high enough rate to pay a return on the investment without working a palpable injustice to the public; and the familiar illustration given is that of a branch railroad built to tap a logging or mining district, where, after the natural resources are exhausted, there is not enough traffic to pay operating expenses, aside from interest on the investment. This is all true, but a problem of this kind should be treated in an entirely different manner. Such a road never is, and never would be, constructed in the same substantial manner as a permanent line built for all time. The entire line and equipment would be of a temporary nature. When such a road is contemplated, it is the promoter's business to take such facts as its temporary character into consideration, and a return must be obtained during the years of successful operation, such as will, at the end of its period of usefulness, have returned the capital to the owners, plus all expenses and a fair rate of interest on the invested capital; and under these circumstances such rate of return should be allowed by public service commissions. In other words,

the entire capital of the railroad must be amortized by the time its period of usefulness is over. If, however, a road has been built, and through unforeseen conditions has ceased to pay a return on the investment, then it becomes a simple question of an unsuccessful business enterprise, with bankruptcy, a receiver, and a winding up of the company's affairs. This is the way a private enterprise would be treated, and there is no reason why a public utility should not be handled in the same manner.

A further objection to this method of treatment may be raised, on the ground that the utility is of absolute necessity to the community, as, for example, a water company supplying water for household use and fire protection. Such an objection is well founded. However, a community cannot compel a company to operate indefinitely at a loss, so, under such circumstances, the community should operate the utility at its own expense until such time as a proper sale value can be placed on the property and the utility is acquired by the community, such value to be founded on "market value," or, in other words, the "bankrupt sale value," and not on either actual cost to date, replacement value new, or any other value.

In many appraisals it will be found that there are often items which, if a fictitious value such as present-day cost is given to them, will lead to embarrassing and often ridiculous results, whereas, if their actual cost is used there is no chance for an injustice, either to the company, to the rate-payer, or to the investor. The following are given as some typical examples:

According to an old print, the great Tring cutting, made on the line of the London and North Western Railway in 1837, was excavated by hand and the spoil was removed in hand-barrows guided by men and pulled up inclines on the sides of the cutting by ropes passing over pulleys and worked by horse-power. If such a piece of work was to be valued by cost of reproduction, should the same conditions be duplicated, only with present-day prices for labor and material, or should it be assumed that the most modern methods would be used, with steam shovels and construction trains? In either event, it would mean entering into the realm of speculation and surmise, when the facts are there before the investigator.

On many of the early railroads built in the United States, temporary trestlework was constructed of timber obtained along the line.

It surely would not be just to estimate a value for such works based on present-day figures for labor and material entering into them.

In developing a water power, it is common practice to obtain the timber for the coffer-dams, and also the sawed and dressed lumber for form work or other uses, from the forest immediately contiguous to the site of the development. The writer knows of cases where such sawed lumber has been supplied at from $10.00 to $12.50 per m. b. m. Later, when all this timber has been cleared off, it would not be equable to estimate such lumber at a price of from $25 to $30 per m. b. m. just because it would now cost the latter figures to obtain it at the site. On the other hand, the cement used in many of the masonry dams in the Western States was obtained at an exorbitant figure. As lines of transportation develop, and markets come nearer these sites of power development, there is no reason why the value of the dam should be placed at a lower figure, because cement can now be obtained cheaply.

Several years ago the cost of a certain class of steelwork, erected in place, was 4.07 cents per lb. Since that time, this price has not been reached, but the same class of work has been done as low as 2.87 cents per lb. (an exceptionally low figure). This is a difference of 29½ per cent. It would not be just to compel the railroad which had paid the higher price to reduce its capital to suit some arbitrary figure which would be a mean between these two extremes. The capital for this work was honestly invested, and no part of it should be wiped out.

In regard to those items mentioned in the first paragraph of Section 2, which should and should not be included as capital in a physical valuation (numbered from 1 to 14, inclusive), it is necessary to discuss some of these more in detail.

Referring to (1), "Promoters' fees", it can readily be explained why this item should be taken at actual cost. This fee depends on the circumstances immediately surrounding the specific case under consideration. What would be excessive under some circumstances, would not be commensurate in others. One of the largest hydro-electric developments in the world was advocated for more than 10 years by its promoters before final completion. Such devotion to an ideal is worthy of more substantial reward than if 6 months or 1 year only was spent in such work.

In some cases the promoter's fee may also include and cover all preliminary work of developing and organizing, in which case the one item only must be included in the valuation. For these reasons, if this item is estimated on a cost-of-reproduction basis, it amounts simply to a guess as to what is equable.

As to those items included in (5), "All overhead charges during construction," there is no way by which they can be estimated on a present-value method with any degree of accuracy. The system usually adopted is to calculate such items as a percentage of the inventory reproduction cost of the utility. Such a figure might be very much less or very much greater than the actual cost. The amount of each of these items depends on the particular enterprise, its period of construction, and the conditions immediately surrounding it. Therefore, they should be included at actual cost only.

In regard to interest on capital during construction, there is one element of this matter which the writer does not recall having heard mentioned by any author on this subject, and which tends to reduce the total interest payable before the completion of the enterprise. This is that final payments on contract work are sometimes not made until the utility is in operation. The writer has drawn up many contracts for construction work on public utilities in which the following clauses were inserted:

"The company shall, however, deduct and reserve ten per cent. from any periodical payments falling due for work done and materials furnished hereunder, to be paid only at the expiration of thirty days after the works shall have been completed, approved, and accepted by the engineer * * *."

"The works shall not be finally approved * * * until all machinery and apparatus furnished hereunder shall have been regularly operated in the manner for which the same are intended to be used for a period of 30 days from the date of starting the same in regular operation * * *."

Referring to Item (7), cases may occur where the new improvements possibly cost less than the original investment. Any cases such as these must be cared for by a fund to cover depreciation, obsolescence, and inadequacy. Referring to the private business, it was seen that such a concern usually charged off a certain percentage of the cost of the plant from year to year, until the capital invested was theoretically all returned. As a public utility corporation cannot do this,

and go out of business at any time at its own volition, the securities covering any such abandoned or superseded property must be retired by withdrawals from the fund set aside for that purpose, unless there are other tangible assets not covered by securities to take the place of the useless property.

Taking up those items which should not be included as capital, and referring to Item (9), it has often been the case in the past that the promoters of the enterprise received such a large remuneration that the company was strangled with overhead charges before it had a chance to start. Such excessive fees must not be included in any physical valuation, and only a fair amount must be allowed under such circumstances.

Thus any excessive salaries of officers or of those in charge of the construction of the utility must not be included. If there has been anything of this kind in the development of the enterprise, only such an amount must be included for this item as such first-class direction and supervision could have been obtained for in the open market.

"Discount on Bonds", Item (11), must not be charged to capital. This item, no matter in what light it is considered, amounts to an increased rate of interest on the capital actually invested. As interest is considered an operating expense, and a sum is set aside from gross receipts to take care of it, so discount (which is only deferred interest) should be taken care of by equal increments set aside from gross receipts from year to year. That is, discount must have been amortized by the time the bonds mature.

Even if the discount includes the brokerage charge, it is still interest that must be met, and so should be amortized as explained previously. The brokerage charge is payment for the use of money; therefore it is a true interest charge and should be treated as such. All commission rulings in regard to this item follow this method in dealing with the question.

Referring to Item (12), it will be noted that early development expenses are excluded. The reason for this is that, according to the writer's view, these are strictly operating expenses. If a utility is properly managed, the development stage never ceases. The training and education of employees for their various duties never end. The advertising department is always attempting to obtain more and

more patronage for the utility. As to errors of design and construction which may develop during the early days of the operation of a utility, and the correction of which so many appraisers claim should be paid for out of capital, these also should be paid for out of profits, if there is money to pay for the work, because there is practically no limit to which such changes can be carried. For example, on railroads expensive tunnels, long cut-offs, great trestles, deep fills, and heavy bridges, are to-day being constructed simply to correct such errors of design and construction; and if such corrections and betterments are to be capitalized as new development, what security is left for the obligations already issued against the original and now abandoned or superseded work? In other words, "development" should be the watchword of every utility, whether in economy of operation, increase in business, or increase in satisfaction of service. The appraiser who attempted to include any such items as early development expenses in a physical valuation, either on the basis of actual cost to date, or present value, would be confronted by a peculiar problem. He would not know where to begin or where to leave off. Even if detailed accounts of the company were open to him, he would be no better off. It would simply be a matter of his personal opinion as to what items of this class of operating expenses he called development expenses, and what he called operating expenses, and his personal opinion, also, would alone be his guide as to where in the corporation's history he would stop charging development expenses to capital and charge them all to operation.

Furthermore, relative to this matter, it is to be remembered that most utilities have been slow in growth, and that it has not been necessary to train forces or build up an organization from absolutely ignorant material to handle the complicated conditions of to-day. For example, in the railroad world, the transition from the small systems beginning in England in 1825 with a few miles of track, tiny cars, and 8-ton locomotives, to the great transcontinental lines of to-day, with thousands of miles of track, cars of 110 000-lb. capacity, and great Mallet compound locomotives, was not made in a single stride. It was a slow development, and the corporations gradually expanded and improved to meet the conditions as they arose.

In regard to Item (13), if a utility has been constructed on a larger scale than is necessary to supply the service properly, then the cost

of such excess size must not be included in the valuation. There is an exception to this, where a utility has made provision for future extension and development to a limited degree; but it must be only to a limited degree. If the utility has made such provision out of all proportion to the needs of the present community, then it cannot expect to obtain rates on the cost of the same. The capital must have been wisely and judiciously invested. (See Smyth *v.* Ames, 169 U. S., 466; Pioneer Telephone and Tel. Co. *v.* Westenhaver, 29 Okl.; 118 Pac., 354; San Diego Land and Town Co. *v.* National City, 174 U. S., 739.)

3.—Real Estate.—In regard to the valuation of real estate, a number of elements enter into this problem, which differ from those affecting the valuation of other tangible property, and, for this reason, this item is generally considered separately.

All public utilities have the privilege of resorting to the rights of the law of eminent domain to acquire property, if such property can be shown to be necessary for the proper development of the enterprise. Thus, an individual, although he may foresee that his property is going to enhance greatly in value in the future, can be forced to part with it on the basis of its value at the time condemnation proceedings are instituted.

Those who uphold the present-value theory of valuation maintain that land should be included at its present value, as determined by the price of similar property in the immediate neighborhood, plus a percentage to cover the expense of what it would now cost the utility to acquire such land. That it costs a utility much more to acquire real property than its actual market value, is now such a well-known fact as to need no argument here.

Such extra cost in the case of urban property consists of legal expenses incident to the transaction, plus the costs of condemnation proceedings, if final resort is made to the law of eminent domain. Also, more particularly in the case of a new utility, there may be the cost of damages to adjoining property, caused by the very fact of the utility being in operation at all. In the case of country property, there is also the cost and value of such elements as temporary and permanent severance damages, plottage, and continuity (the three latter items applying more particularly to railroads). As all such extra values and costs are known to the average seller, he asks such

a price, over and above the fair market value of the land, as he thinks the corporation will pay, without resorting to condemnation. As time is of very great importance, and condemnation is apt to be a slow process, the corporation is generally willing to pay even more than this would cost.

For city property, the percentage of increased cost to the utility runs from 120 to 300%, and, in the case of country property, from 200 to 800% of the fair market value of such property without improvements.

In discussing this question, the following facts are to be kept in mind: In the case of many utilities, especially the railroads (our leading public utilities), land was purchased, even in the cities, at a very low figure. In many cases, large grants of land were made to the railroads, sometimes by individuals and communities for right of way and station sites, and by the United States Government for similar purposes. In addition, in some cases, large tracts were also given by the Government simply as a bonus for building the railroad at all. All such grants were made on the understanding, if not specifically stated, at least implied, that the corporation was to return useful and satisfactory service in some form to the community.

Almost without exception, the value of such land, whether obtained by purchase or gift, has increased enormously, such increase having been caused in large measure by the very fact of the utility being there at all. All utilities now claim that they should be allowed to include in a physical valuation all such land, not only at its increased value, but also at a value obtained by increasing such present market value by the same proportion as the original value of the land was increased in cost to the utility. In other words, the utility corporation wishes to put all conditions back as they would be without the utility, except the greatly increased value of the land, then assume that the utility wishes to acquire such land, and must go through all the processes to do so, increasing the value of the land by the percentage as already determined, and this to apply whether the land in question was obtained by donation or purchase.

To make this perfectly clear, assume the following concrete case. Land at a value of $100 per acre was acquired by a utility corporation at a total cost of $250 per acre, or 2½ times its market value, and adjoining land of the same value was also donated to the company.

All such land is now worth $1 000 per acre. The contention of the corporations is that all such land, including that donated, should be included in a valuation at a price of $2 500 per acre.

Even if an appraisal is being made on a present-value basis, the writer fails to see any logic or justice in such a contention. If the land is to be included at its present value and such value is high enough to cover all the original cost of acquiring it by the corporation, then no multiplier whatever should be used. In other words, the utility corporation, in the case of land, wishes to assume a set of theoretical conditions that could not by any possibility exist, and then found value on such conditions. It is these very elements that are so severely criticized and condemned in the Minnesota Rate Cases (230 U. S., 352) and that were decided against the utility corporations.

As a further example, suppose a community has presented a station site to a railroad. The corporation claims the right to ask rates on the value of such property and to issue securities against it; but, as rates are supposed to be a return on capital invested, and as securities are supposed to be issued to obtain capital to build the road, how, by any possible process of logical reasoning, can donated property be used for such purposes?

How untenable this present-value theory of land is can be demonstrated by illustrating an extreme case. Assume that a railroad had acquired terminal facilities in a city years ago, when land in the immediate vicinity of such property was cheap and unimproved. Now, suppose that the neighborhood improves, that the city grows up to and surrounds the terminal, and that the adjoining property becomes improved with expensive hotels and office buildings (this assumption is a fact in many cities). It would surely not be equable to value such terminal land for rate or security issue purposes on the theoretical supposition that it was all, or any part of it, occupied with such buildings, and that the public utility corporation (the railroad) must now pay the full value of such land, with all the improvements thereon to date, in order to acquire it. On the other hand, if, in order to provide for necessary extensions, the corporation was compelled to purchase any such land with such improvements thereon, then, even though the improvements were destroyed, the land should be valued at the total cost to the company.

Therefore, land or real estate should be included in any physical valuation on the same basis as any other property.

4.—Depreciation, Obsolescence, and Inadequacy.—In discussing the matters of depreciation, obsolescence, and inadequacy, most appraisers seem to take the stand that some definite scheme must be decided on at the commencement of the operation of the utility, and adhered to without any change, by which its total value will be returned to the owners at the end of some fixed period, which is as near as may be the end of the useful life of the plant. The following theories have been developed to produce this result:

(1) Replacement method for depreciation;
(2) Sinking-fund method for depreciation;
(3) Straight-line method for depreciation;
(4) Equal-annual-payment method for depreciation.

It is not necessary to discuss these methods separately. The trouble with all of them is, that, in order to work them out and discuss them at all, it is necessary to assume conditions in regard to the life of the plant and its operation, which, in practice, from the very nature of a public utility property, cannot be realized. These assumptions are as follows:

(1) That the physical plant of the utility, or at least its component parts, have a definite life;
(2) That the value of the plant must have been returned to the owners at the end of this period;
(3) That the owners must reinvest this returned capital at the end of the period in a new plant.

These assumptions are fundamentally wrong. It is impossible to give exactly the life of any parts of a utility; therefore, it is impossible to set aside or accumulate exact amounts to replace them. The best that can be done is to assume some term of years, based on former experience with the physical element under consideration. In addition, new developments, discoveries, and inventions, may, almost over night, cause valuable machinery and equipment to be consigned to the scrap heap, and thus the element of obsolescence comes into being. Conditions may change slowly or suddenly, so that the equipment of a utility becomes inadequate to handle the conditions as they

now exist. Thus, inadequacy is "developed." As an example of the former, the machinery of the cable roads in New York City had to give way to electric traction long before it was worn out. To illustrate the latter, there is the necessity for larger cars to handle the increasing traffic in large cities, or the necessity of railroads replacing wooden cars with steel, before the former have served their physical period of usefulness.

If the value of the plant was to be returned to the owners at the end of its period of usefulness, there would be a time, between the end of the old plant and the beginning of operation of the new, when there would be no utility. A utility, however, cannot go out of business of its own volition. It must continue to give good and useful service to the community (see Weatherly *v.* Capital City Water Co., Ala. 22 So., 140; Judge Haight in People *ex rel.* Manhattan Ry. Co. *v.* Woodbury, 203 N. Y., 231; 96 N. E., 420).

Therefore, in regard to depreciation, obsolescence, and inadequacy, such elements in the maintenance of any public utility should be taken care of by a fund maintained for this express purpose. This fund should be accumulated from a yearly increment taken from gross receipts and charged to maintenance costs. With a very few exceptions, every element in a utility begins to depreciate from the moment the construction forces place it in position. In a general sense, obsolescence and inadequacy are also depreciation. The utility should be kept up to date and up to 100% efficiency and value by constant withdrawals from this fund, to make good the three classes of deterioration previously mentioned. Therefore, at no time should such a fund amount to a very large percentage of the cost of the plant.

In order to maintain the fund in an equable manner, the amounts placed to its credit must, as far as possible, be evenly distributed over the years of the operation of the utility. There is no reason, however, why such amounts may not vary from year to year within reasonable limits, or why some definite plan should be fixed on and adhered to for a term of years, in order to accumulate such a fund, without any regard to conditions and circumstances which may develop or change in regard to the actual physical property.

It is impossible always to have an exact balance between the actual depreciation on the one hand, and the amount of the fund on the other. The fund, however, should be kept as near as may be to such

an amount. If such a fund is actually kept in trust for this purpose, there is no question but that it should be treated as an item of the plant, and rates should be allowed on it. However, if no such fund exists, or if it exists only in theory on the books of the corporation, then, in a valuation of the utility, depreciation may become a very important item, and must be given careful consideration. This may be treated in the valuation in one of two ways, which lead to the same result: The property may be appraised at its full cost, without depreciation, and returns may be allowed on this figure, no special mention being made of the depreciation fund; or the property may be appraised at its cost, less depreciation, and returns may be allowed on this and also on the depreciation fund.

That utility corporations are expected to keep the plant in first-class condition by constant withdrawals from some such sinking fund or its equivalent, and without allowing any excessive accumulation of such a fund, is set forth in Knoxville *v.* Knoxville Water Co., 212 U. S., 1; Cumberland Telephone and Telegraph Co. *v.* City of Louisville, 187 Fed., 637; and People *ex rel.* Manhattan Railway Company *v.* Woodbury, 203 N. Y., 231.

5.—Going Concerns and Franchise Values.—There are no other matters in the appraisal of a public utility that are so difficult of a fair and equable solution as the values to be given to the intangible elements, going concern and franchises. More difference of opinion exists among appraisers in relation to the method of treatment of these items than in regard to any others of the entire subject, some maintaining that no value whatever should be placed on them, others saying that as well not value the utility at all, as to omit them.

As to going concern value, there is nothing tangible that has ever entered into it, except the general management of the company. On the other hand, however, it is an admitted fact that the mere cost of the bare physical property of a utility does not represent the full value of a concern that is organized, managed, and operated in an efficient and satisfactory manner.

Various attempts have been made to arrive at some equable method of obtaining an equivalent tangible value for this intangible element, the best known of which is the capitalization of earnings over and above a fair return on the actual invested capital. In a physical valuation for the determination of rates, as the going concern value

deduced by this method depends on net income, and net income depends on rates, which is the very thing that is to be determined, it is impossible to obtain any such value in this way. Any attempt to deduce going concern value from rates, or to found rates on going concern value, is simply reasoning in a circle.

If this question is referred to the private business for study and comparison, the writer thinks that an equable solution of it may be deduced; and, as far as he knows, such solution has never been propounded before.

The private individual never charges up any value for going concern on the credit side of his balance sheet. What he does is this: In order to determine a price at which he can dispose of his commodity profitably, he first figures the total actual cost to produce the article (including amounts to cover depreciation, etc.), or, in other words, the "operating cost." The next item he adds to this cost is a fair rate of interest on the actual cost investment in the plant, and then follows an item to cover the general risk of the business. Lastly, he would add a figure to cover the fact that he is in business at all, or, in other words, that his concern is a "going" one, with all the advantages that this term implies. This, coupled with the risk item, is his profit in the venture.

There is no valid reason why the returns to the owners of a public utility corporation should not be determined in the same way. The operating expenses, including an allowance for depreciation of all kinds, are known or estimated, the physical cost has been determined, and a rate of interest must be allowed on this tangible value, such as the same amount of cash would return if placed at ordinary rates of interest. In addition, a further rate must be allowed to cover the risk of the enterprise.

Now, coming to the fact that the utility corporation is a going concern, in exactly the same way as the private enterprise is, there is no reason why the return for this intangible element cannot be equably obtained by adding some percentage to the figure already determined to cover the items before mentioned. In other words, these two items—the risk and the going concern—are the "profits" of the enterprise, and are so intimately related in practice as to be almost incapable of separation. In one sense, ordinary interest cannot be considered a profit, as such return could be obtained without any

investment in the utility. If there is no going concern, there is no profit, and, therefore, the return for going concern is covered when a fair rate (profit), over and above enough to cover expenses and ordinary interest, has been allowed.

Objections may be made to this method on the ground that it is impossible to determine any standard figure by which to gauge all cases in which going concern value must be determined, and that it really amounts simply to the opinion of the appraiser as to what to use. Such an objection, however, applies with equal force to any system whatever for estimating the value of going concern. In any event, the determination of a figure is simply a matter of the personal opinion of the appraisers as to what is an equable value for this element, and it is a much simpler matter to decide on a percentage of the actual physical investment in the plant, to cover it, than to go through an intricate set of calculations which are purely arbitrary and only tend to befog the real issue in the case.

If a valuation is made for the purpose of issuing securities, inasmuch as securities are issued, at least theoretically, to obtain capital to build and operate the utility, and going concern value cannot enter the problem until after the utility is in operation, therefore, no consideration should be given to this item for such purposes.

It is often assumed that franchise value and going concern value are so closely related as to make it impossible to separate one from the other for purposes of valuation. There is no doubt that these two elements are very intimately connected, but, at the same time, the writer thinks that there is enough material difference to make it very apparent why the two should be separated for purposes of discussion. A franchise is simply a permit, or the grant of the right, to conduct the business at all. On the other hand, going concern value is a value resulting from the use and application of the rights and privileges granted by the franchise. A concern may possess a franchise, which in itself is valuable, but on account of mismanagement and incompetency, the business may have no going value.

If a franchise only runs for a limited number of years, it has less and less value the nearer its time of expiration approaches. When it has expired, of course it has no value, although, under these conditions, the Courts have held that there is still a going concern value

in the property. (National Water-Works Co. *v.* Kansas City, 62 Fed., 853; Omaha *v.* Omaha Water Co., 218 U. S., 180.)

Furthermore, there may be a tangible element of value that attaches to a franchise from the fact that money may have been expended in a perfectly legitimate way to take the necessary steps to obtain it; or a franchise may have been purchased from a municipality, or by one company from another company. Thus, there may be a tangible element to take into consideration in the valuation of a franchise that does not occur in going concern value.

Although all franchises were granted by the State, the consensus of all Court rulings is that, once the grant having been made, and the corporation having expended capital under the implied protection of such grant, the State cannot revoke the franchise without giving to the corporation full and just compensation for its value. Just what value this is, no one has yet been able to determine. Every case has simply been decided by recourse to some arbitrary figure.

As far as rates are concerned, as the franchise is only the permit to conduct the business, if a fair return has been allowed for risk and going concern, that is all that is just and equable, and no special provision should be made for the franchise value, except in so far as actual expenses have been incurred in obtaining the same.

6.—Valuation for Purchase or Sale.—If a utility is to be valued for the purpose of purchase or sale, either between companies or between a company and a community, in the absence of a special agreement to the contrary, the present or fair value (in the majority of cases, cost of reproduction less depreciation) is the just and equable figure to be used for this purpose, except as hereinafter noted. Actual cost should be used simply as a guide in arriving at this figure.

By referring back to the paragraphs dealing with the sale of a private business, and applying the same reasoning to the utility corporation, the writer thinks that the justice of this method under these conditions will be perfectly apparent. The security holders have a perfect right to have the full value of the plant, as it stands at the time of sale, returned to them, as this is the figure it would cost the purchaser to reproduce it. Conversely, if the plant is now worth less than when it was built, the purchaser is entitled to the reduced price, as he could now build a similar plant for this figure. No purchaser has any grounds to say to a seller that he must part with his

goods at a less price than they would bring in the open market; nor has the seller a right to expect a higher price under similar conditions.

There are some exceptions to this use of the present value for some items, in cases where a community is the purchaser and the seller is a corporation that has exercised its functions under a charter granted by said community. These items are those of going concern and land values.

In regard to going concern value, the doubt as to the justice of allowing an amount to cover this item under the foregoing conditions arises from the fact that the community generally claims that, the franchise having expired, or being about to expire, and the corporation being about to go out of business, there is no value left for going concern. On the other hand, the corporation claims that, as the community is going to obtain a plant fully developed and in full operation, it is very different from starting up a new enterprise from the beginning, and that there is, therefore, a perfectly legitimate value to going concern.

The truth of the matter is that both parties to the controversy are partly right and partly wrong, and the only equable solution is to follow a middle course and allow some value for the going concern, but not such a large figure as the corporation would undoubtedly ask. Following such a course is the way the Courts have attempted to decide this difficult question (National Water Works Co. *v.* Kansas City, 62 Fed., 853).

As to land values, here also, under similar conditions of sale, it may not be equable to charge the full reproduction cost. The reasons for this in the case of land are perhaps not as apparent as in that of going concern, but the following are set forth as some limiting considerations:

If a utility is being appraised for purposes of sale, it may be that although the land now has a high value, other land could be obtained for the same purpose at a greatly reduced price, that would be just as satisfactory; but, as the utility cannot be moved without the destruction of the plant, it is impossible to separate the land from the utility. Furthermore, the land may have been obtained by recourse to the law of the right of eminent domain, and owners thus forced to part with their property against their will, when they may have realized that they were losing a good investment. It does not seem

equable that they or their immediate descendants should be compelled to pay a greatly increased price under such conditions.

In a case such as the foregoing, if the sale was one between private interests, it would simply mean that the buyer would go where cheaper land could be procured, if an exorbitant price were demanded by the seller. Both the buyer and seller are free agents, and are not compelled to enter the transaction against their will. In the case between the community and the public utility company, however, as the latter is and has been a monopoly, and for good and valid reasons either one or both of the parties may have been compelled to enter the transaction against their will, the solution of this part of the problem must be treated along somewhat different lines from that of other tangible property. There is only one seller and only one buyer, and no open market.

Under such circumstances, each case must be solved according to its own merits. It would seem here, as in the case of going concern values, that a middle course must be followed which will give as equable a solution as possible to both parties.

7.—*Valuation for Taxation.*—For the purposes of taxation, it does not make any difference what value is used, if the utility is under full State control, except that it might favor one section of the country as against another—this applying more to the railroads than to any other utility.

This can be explained as follows: The utility being under State regulation, all operating expenses are allowed over and above any return on the investment, and taxes are classed as an operating expense. If a local section of a road is assessed at a high valuation for purposes of taxation, and most of the revenue is obtained from through traffic, this traffic would then have to pay these taxes, to the benefit of the locality; but if the utility is a local one, there is no difference one way or another. The taxes come from the people in the form of operating expenses, and are returned to them as taxes, be the assessed value high or low, or the taxes on the assessed value high or low.

IV.—Conclusion.

There are some phases of the public utility corporation that the writer has not considered it necessary to discuss, inasmuch as they have no direct bearing on the valuation of the property of these com-

panies. Such, for example, is the company organized simply with the idea of acquiring and holding the securities of public utility corporations, now known as a "holding company," which class of concern is at present being severely criticized by the public and the States. A number of questions, also, that are being debated at the present time, such as the agency theory as applied to corporations in their relations to the State, and whether a public utility has the right to invest surplus profits, or a depreciation or amortization fund, in new construction and additions to the plant, and then charge rates on such investment, have not been touched upon. In addition, some physical elements, such as piecemeal construction, solidification and adaption of roadbed, pavement over mains, working capital, etc., have not been discussed in detail. The reasons for these omissions are that it is impossible to discuss every question that may have a bearing on the physical valuation of the property of public utility corporations, within the limits of this paper.

Furthermore, no attempt has been made to quote all legal decisions that may apply to the subjects discussed, nor has any attempt been made to give decisions in support of all contentions and arguments. Only enough have been given to show the general trend in the more important cases.

As was stated in regard to the private business, so also every public utility is capable of endless modifications and variations in its details of organization, the conduct of its affairs, and its relations to and with the State. When all is said and done in regard to the control and valuation of these corporations, every case must finally be decided on its own merits, and with due regard to the conditions and circumstances immediately surrounding it.

The real object of a valuation of any public utility is to obtain a figure such that any calculations or regulations founded on it as a basis will be just to all parties that have any interest whatsoever in the matter.

In the foregoing pages, the private business, the private corporation, and the public utility corporation have been outlined and compared; and, based on the similarity and the dissimilarity of such corporations with the private business, it has been shown how the property of these companies may be valued for different purposes. Broadly speaking, as far as the actual physical business is concerned, there is no difference

between the public utility corporation and the private business, and it is for this reason that a physical valuation of the property of a company of this class should follow the general lines that a private business would use in its accounting systems. There is no reason why there should be any difference in this respect between the two, except where elements are introduced into the problem that arise from the monopolistic character of the public utility.

On the other hand, however, it has been shown how the public utility corporation as an organization is, in its very inception, entirely different from the private business and the private company, and, on account of these methods of organization and development, how its relations with the State are of necessity on an entirely different status from those of the latter concerns. These main points of difference are here summarized as follows:

1.—The public utility corporation, before engaging in business at all, must obtain special favors from the State.

2.—It enters into direct business relations with the State.

3.—It therefore becomes the agent of the State.

4.—After having once entered into such an agreement with the State and accepted the trust, although it now has invested its own capital (property) in the enterprise, it cannot withdraw from the agreement on its own volition.

5.—Such invested property is held under different conditions and circumstances than that invested in private enterprises.

6.—It is a monopoly granted and, with certain limitations, upheld by the State.

7.—It is for these reasons that the State has the right to exercise detailed control over the public utility.

Therefore, in making an appraisal and valuation of the property of public utilities, if the points of similarity between this business and the private business and private corporation are kept constantly in mind, it will be seen why actual cost to date is the basic figure to be used in all cases, as has been set forth in the foregoing paragraphs; and, if this figure is used, it eliminates, as has been shown, many of the elements in such work that seem to be so difficult of solution. Actual cost is a figure equable to the investor (the real owner), to the promoters, to the managers; and last, but by no means least, such figure is absolutely just and equable to the public at large.

INVESTIGATION OF THE PERFORMANCE OF A REACTION TURBINE.*

By R. L. Daugherty, Esq.†

Synopsis.

A careful and accurate test of a 550-h.p. reaction turbine recently installed at Cornell University showed a very high efficiency. In addition to the regular load test at constant speed, the torque, head, and discharge were measured at zero speed, and readings were also taken of speed, head, and discharge under no load. From these data it was possible to construct, at least approximately, a complete characteristic curve for the turbine.

1.—Cornell University generates its power for lighting and other purposes in a hydro-electric power plant which operates under a head of approximately 140 ft. The water is led from Beebe Lake to the power-house through a pipe line 5 ft. in diameter and 1 711 ft. long. When the present power-house was built, in 1905, it was equipped with four Pelton impulse wheels, but the increasing demands for power have made it necessary to add to the capacity of the plant. After due consideration of the various factors involved, it was decided to put in a reaction turbine for the additional unit.‡

*This paper will not be presented at any meeting of the Society, but written communications on the subject are invited for subsequent publication in *Proceedings*, and with the paper in *Transactions*.

†Assistant Professor of Hydraulics, Sibley College, Cornell University.

‡"Choice of Turbine for University Power House", by R. L. Daugherty, *Sibley Journal of Engineering*, Vol. 28, p. 191.

2.—The turbine selected was made by the I. P. Morris Company, of Philadelphia. It is rated at 550 h.p., at 600 rev. per min., under a head of 142 ft. The runner is 27 in. in diameter. The turbine is direct-connected to a 450-kv-a., 2 300-volt, 3-phase, 60-cycle alternator, supplied by the General Electric Company.

3.—The new turbine was tested by the writer in February, 1914. In this work he was ably assisted by Mr. F. G. Switzer, a graduate student and Fellow in Sibley College. The latter calibrated all the electrical instruments used and took charge of the determination of the generator output and efficiency.

4.—With the data secured in this test, it was possible to construct curves which would show the operation of the turbine under any combination of head, power, and speed. This is rarely done except in the case of a brake test. On account of the favorable conditions for testing, it is believed that a higher degree of accuracy than usual was attained. The efficiency of the turbine itself was found to be very high.

5.—The method of estimating the head in a turbine test is a matter of agreement in any case. The head consumed by the wheel alone is the fall from the surface of the head-water to the surface of the tail-water, minus all losses in the penstock and draft-tube. It is usually obtained by taking the difference in the heads at the entrance to and exit from the turbine. Let the pressure, when reduced to feet of water, be denoted by p, the elevation in feet above any arbitrary datum plane by z, and the velocity, in feet per second, as determined by the cross-sectional area and the measured rate of discharge, by v. If subscript $(_1)$ be used to indicate values at the point of entrance to the turbine case and subscript $(_2)$ corresponding values at the point of discharge from the turbine into the draft-tube, the head on the turbine will be:

$$h = z_1 + \frac{v_1^2}{2g} + p_1 - z_2 - \frac{v_2^2}{2g} - p_2.$$

6.—The draft-tube is often regarded as an integral part of the turbine, and thus any losses connected with it are to be charged to the turbine. Thus, the head on the turbine and draft-tube will be the fall from the head-water to the tail-water, minus the loss in the penstock

FIG. 1.—CORNELL UNIVERSITY POWER-HOUSE.

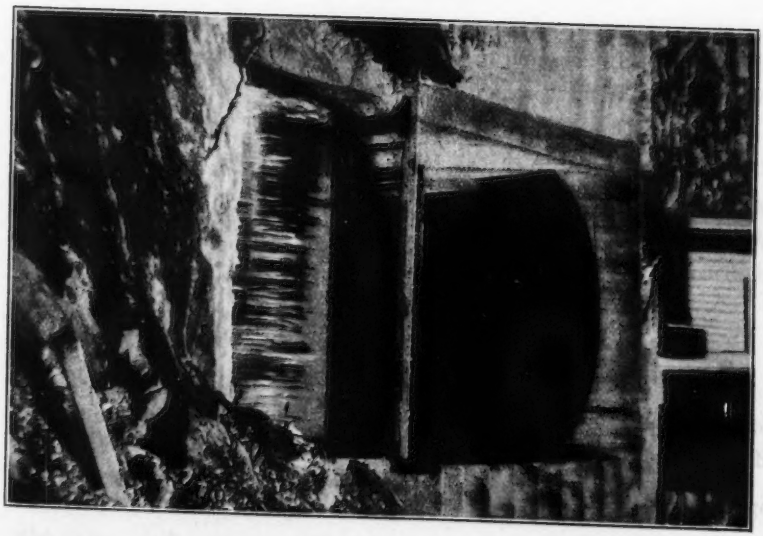

FIG. 2.—WEIR IN TAIL-RACE.

only; or, it is obtained in a test, if z_1 is the elevation of the point where the pressure is measured above the tail-race, by

$$h = z_1 + \frac{v_1^2}{2g} + p_1.$$

This value of h will be greater than that given by the equation in Paragraph 5. The difference between the two is equal to the friction head in the draft-tube plus the velocity head lost at the discharge from the mouth of the draft-tube. To illustrate this it might be noted that for Run 7 the head computed by the method shown in Paragraph 5 was 137.9 ft., and, as computed by the method just given, it was 140.46 ft. Throughout this paper the latter method will be used.

7.—In the test the pressure at the intake was measured with a mercury column built in the form of a U-tube. The height of the mercury columns was read on a metal scale graduated to hundredths of a foot. The oscillation of the columns was usually less than 0.010 ft., so that accurate readings were readily secured. There were four pressure connections equally spaced around the circumference of the penstock, and the true pressure was taken as the average of the four readings. It was noted, however, that there was very little difference in the pressures as measured at the four points.

8.—For convenience, the pressure was transferred to the center of the shaft which was 3.82 ft. above the zero point on the metal scale. If the two mercury column readings be denoted by R_1 and R_2, the pressure transferred to the center of the shaft will be

$$13.57\ (R_1 - R_2) - (3.82 - R_2).$$

The vertical distance from the center of the shaft to the crest of the weir was 14.0 ft. If the head of water over the weir be noted by H, the elevation of the center of the shaft above the tail-race level will be

$$14.0 - H.$$

The sum of these two expressions will be the value of

$$z_1 + p_1.$$

The intake pipe at the point where the pressure was measured is 30 in. in diameter. From this area and the measured rate of discharge, the value of v_1 may be obtained. By adding $\frac{v_1^2}{2g}$ to the above, we get the value of the head on the turbine.

9.—The rate of discharge was measured with a suppressed weir in the tail-race. A steel plate with a sharp beveled edge in good condition was set in just before the test. The length of the crest was 7.573 ft., and its height above the bottom of the channel was 2.83 ft. A set of baffles was inserted just below the draft-tube, and a raft was floated on the water to kill the surface ripples. The head on the weir was measured with a hook-gauge. The zero was set by a surveyor's level and checked by an observation when the water was just ready to flow over the weir. At the conclusion of the test, the zero was again checked by the level. During the test there was a small constant leakage through the other wheels. This was determined by a leakage run before the test was begun.

10.—The rate of discharge was computed by the modified Francis formula:

$$q = 3.33\, L \left(H + \frac{v^2}{2g}\right)^{\frac{3}{2}}$$

where,

q = cubic feet per second;
L = length of crest, in feet;
H = head on weir, in feet; and
v = velocity of approach, in feet per second.

If the velocity of approach is uniform over the entire cross-section of the channel, this formula is reasonably correct. In many cases, however, the actual velocity near the surface is much greater than the mean velocity, and there is practically a dead-water space near the bottom of the channel. Thus the effective velocity head is greater than that determined from the mean velocity. As v is obtained by dividing the rate of discharge by the cross-sectional area of the channel, it is customary to multiply $\frac{v^2}{2g}$ by a factor which may range from 1.0 to 2.0, according to circumstances. In this case a traverse of the channel with a current meter, by E. W. Schoder, Assoc. M. Am. Soc. C. E., and Professor Turner, showed a uniform distribution of velocity, and thus justified the use of a factor of unity.

11.—This uniform distribution of velocity is probably due to the fact that the distance from the draft-tube to the crest of the weir is only about 30 ft. The draft-tube is vertical, and discharges its water

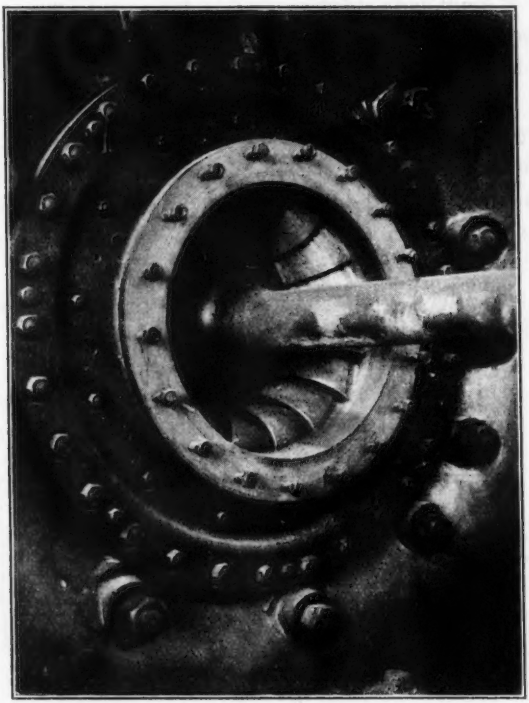

FIG. 3.—REACTION TURBINE, WITH DRAFT-ELBOW REMOVED, SHOWING RUNNER.

FIG. 4.—WATER RHEOSTAT.

directly against the bottom, thus it is probable that there would be a high bottom velocity for some distance. If the tail-race had been much longer we might then have expected to find the more usual (that is, unequal) distribution of velocities.

12.—The power output of the generator was absorbed by a water rheostat suspended in a pool in the creek. This rheostat consisted of three pipes at the vertices of an equilateral triangle, with sheet-iron plates bolted to them. The load was varied by changing the depth of immersion. A similar rheostat, used in some testing in 1913, proved to be very satisfactory, giving a perfectly steady load. The one used in this test was designed to carry twice as much load as the former instrument, but it failed to do so without modification. The design of such a rheostat seems to be largely a matter of trial, in view of the limited data available and also on account of the important factor of

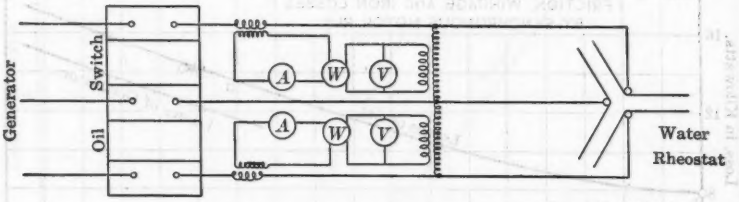

DIAGRAM OF CONNECTIONS

FIG. 5.

the purity of the water.* At the time of the tests in 1914, the run-off in the creek was mostly from melting ice and snow and therefore purer than the ground-water encountered in 1913.

13.—In order to make the rheostat carry the load, it was necessary to bend the plates so as to bring them within 2 in. of each other. It is probable that the fluctuations on the heavier loads were due to the boiling of the water between the plates. By taking readings every 2 min. during quite a period of time, it is believed that a good average was obtained, despite this slight unsteadiness. The accuracy of the results is roughly checked by the fact that the power factor remained approximately constant for all the loads.

14.—All electrical instruments used were carefully calibrated by comparison with standards in the possession of the Physics Department of Cornell University. The ratios of current and voltage trans-

*See *Power*, August 4th, 1914, p. 184.

formers were determined as well as the phase angles of the latter. The phase angles of the current transformers were found to be negligible.

15.—At the end of each run the resistance of the armature was determined by the drop-of-potential method. The friction, windage, and iron losses were found by operating the generator as a synchronous motor. It was also desired to find the value of the friction and windage alone, and to determine how these losses varied with the speed. As this could not be done with the synchronous motor run, a small, direct-current motor was belted to the set. The input to the motor was read, and the motor losses were deducted. If the power of this motor had been sufficient to drive the set at 600 rev. per min.,

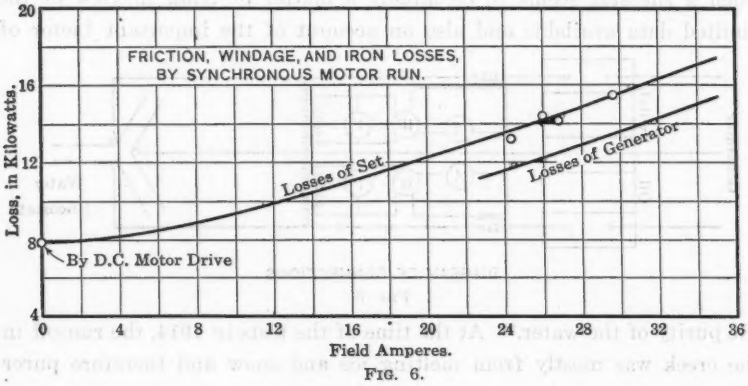

FIG. 6.

under full field, the synchronous motor run would have been unnecessary. The two combined, however, gave everything that was desired. (Figs. 6 and 7.) The friction and windage of the generator was arbitrarily assumed to be three-fourths of that of the set.

16.—In the test, runs were made under various loads at a constant speed of 600 rev. per min. The turbine was also prevented from rotating, and the torque at various gate openings was measured by a system of levers and standard weights. The gate-openings were the same as those used in the load runs. Readings were also taken of head and discharge. In addition, the turbine was permitted to run at run-away speed, the only load on it being the friction and windage of the generator. For the same gate openings, readings were taken of speed, head, and discharge.

17.—The usual commercial test, made at a constant speed and under an approximately constant head, is quite valuable, yet it is not entirely satisfactory. The question is always open as to what the effect would have been if the speed had been a little higher or a little lower. Also, in many plants, where the speed of the turbine must necessarily be constant, the head will vary through quite a range, due

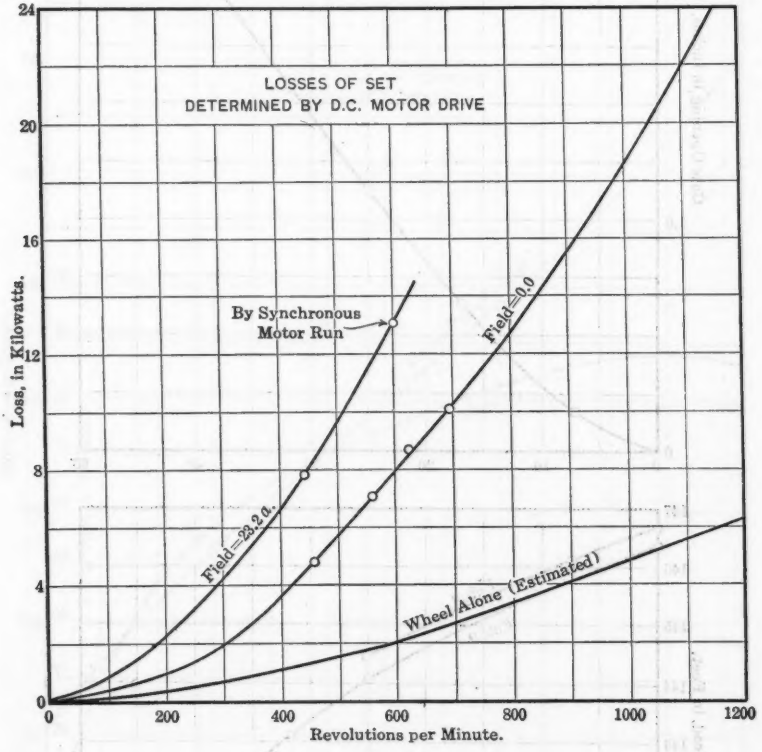

FIG. 7.

to fluctuations in the stream flow. Thus, in actual operation the relation between speed and head may not always be the best. In order to determine fully the characteristics of a given turbine, it is necessary to test it at various gate openings under several relations of speed to head. It is clear that the speed may be varied, as in the usual brake test, or it may be possible to vary the head. Either method will accomplish the desired result. In the test under discussion the head

FIG. 8.

was throttled down by the gate-valve to about two-thirds of its normal value. A load run was then made under the regular speed of 600 rev. per min. It was hoped to secure a number of such points at several

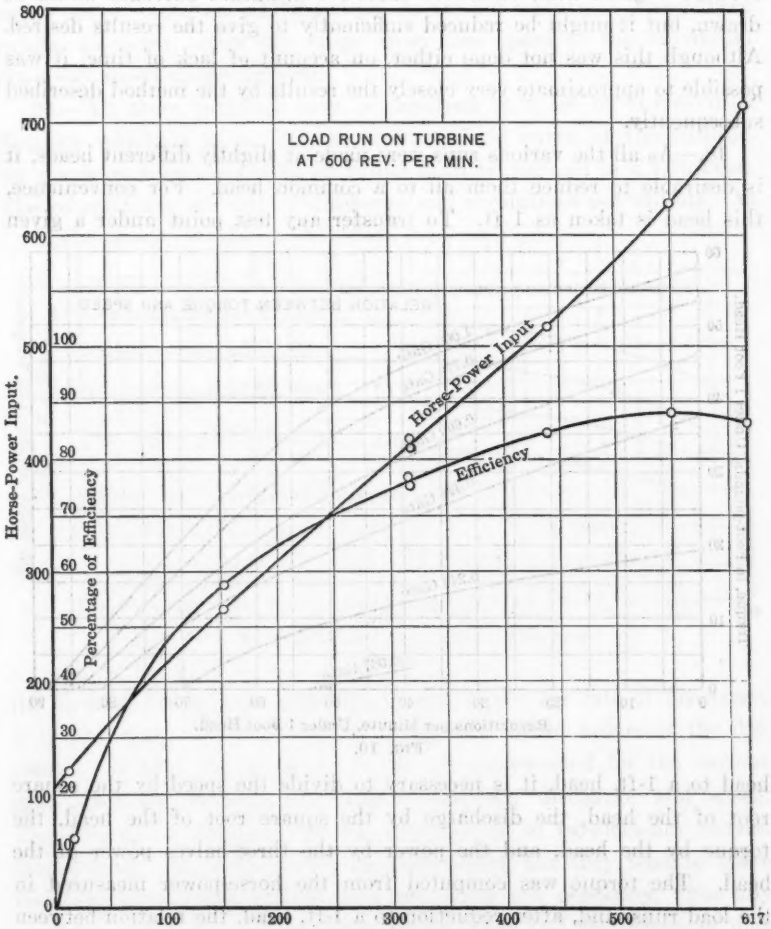

FIG. 9.

gate-openings and at several values of the head, but lack of time available for the test prevented. By throttling the head, while keeping the speed constant, we obtain values higher than normal of the ratio

of speed to head. In order to obtain values of this ratio lower than normal, the head could be made the maximum value possible and the speed of the generator reduced. Of course, the speed could not be reduced a great deal, otherwise excessive armature currents would be drawn, but it might be reduced sufficiently to give the results desired. Although this was not done either, on account of lack of time, it was possible to approximate very closely the results by the method described subsequently.

18.—As all the various runs were made at slightly different heads, it is desirable to reduce them all to a common head. For convenience, this head is taken as 1 ft. To transfer any test point under a given

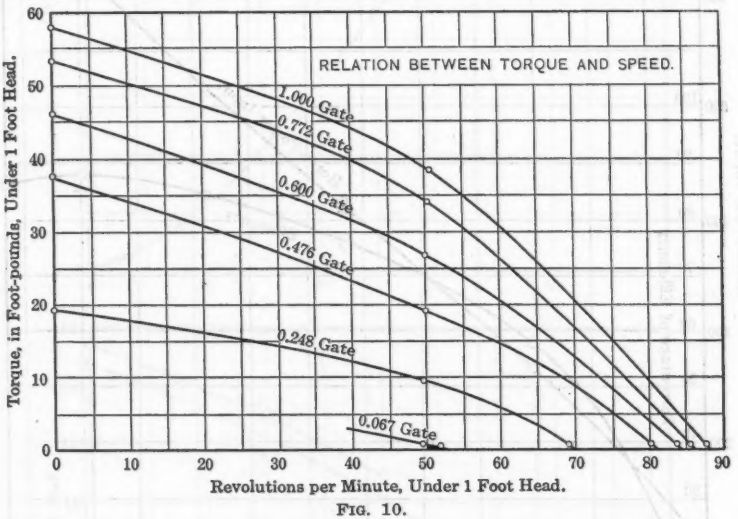

FIG. 10.

head to a 1-ft. head, it is necessary to divide the speed by the square root of the head, the discharge by the square root of the head, the torque by the head, and the power by the three-halves power of the head. The torque was computed from the horse-power measured in the load runs, and, after reduction to a 1-ft. head, the relation between torque and speed is obtained, as shown in Fig. 10. The relation between rate of discharge and speed is shown in Fig. 11.

19.—The relation between torque and speed, or discharge and speed, is not a straight line, but, if a suitable scale is chosen, may be represented by a fairly flat curve. With the three points determined for

each gate opening, it is possible to draw curves which cannot be very far from correct, assuming that the three points are accurately determined. If additional points had been determined by the methods previously outlined, there would then have been no question about the entire curve; but these additional points are not essential. These three points, moreover, cover the range from zero speed to the maximum run-away speed under no load.

20.—All these relations may be involved in a set of curves in a diagram which is known as the characteristic curve of the turbine. To construct such a diagram all values must be reduced to a 1-ft. head. The co-ordinates are rate of discharge and revolutions per minute. As

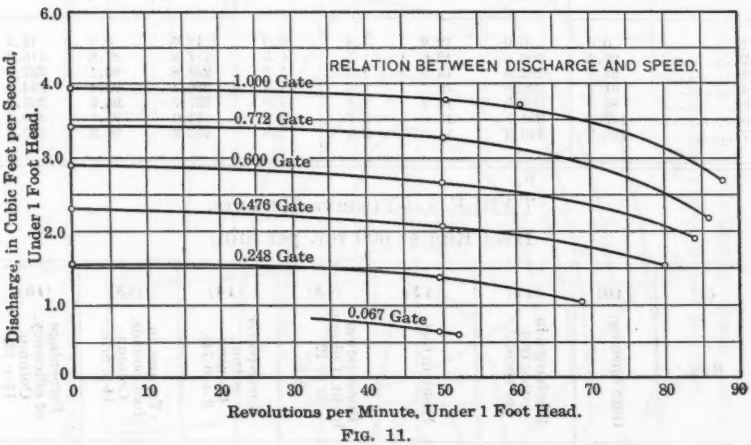

FIG. 11.

the horse-power input is directly proportional to the rate of discharge, it is customary to add a scale for it, parallel to the values of the discharge. Within this diagram, curves are constructed for the various gate openings, showing the relation between discharge and speed. The diagram is completed by the construction of iso-efficiency curves. Occasionally, iso-power curves are also added, but they tend to make the diagram too complicated, and are really not necessary. For any conditions of operation, the horse-power input and the efficiency may be readily noted on the diagram. The product of the two gives the horse-power developed. This system of plotting a turbine performance was devised by D. W. Mead, M. Am. Soc. C. E., and is given in his "Water Power Engineering".

21.—Accepting the curves in Figs. 10 and 11 as correct, the efficiency may be computed at any intermediate point, and thus the characteristic curve may be constructed, as shown in Fig. 12. Such a diagram covers every possible condition under which the turbine may operate.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

THE DIFFERENTIAL SURGE TANK.

By Raymond D. Johnson, Esq.

To be Presented December 2d, 1914.

Synopsis.

It is believed that a good practical working knowledge of the surge tank problem is a valuable asset to the modern hydraulic engineer. The writer has gathered together, in the past twelve years, many useful formulas, has made a thorough study of the subject, and takes this opportunity of presenting a concise analysis to his fellow engineers for their consideration and criticism. Mr. Roy Taylor, the writer's assistant, has been sufficiently interested to give up months of his time patiently to work out illustrative examples, and his criticism should be carefully read as a necessary adjunct to this paper.*

The ordinary simple surge tank, or storage reservoir, which is commonly placed at the end of a long pipe line, has been entirely neglected in this paper, for four reasons which experience has demonstrated:

First.—It never costs less than the differential type for approximately the same benefit realized.

Second.—It can seldom be made quite so effective as the latter type, even at a greatly increased cost.

Third.—It is not capable, to anything like the same degree, of a rigid mathematical treatment.

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

* For Mr. Taylor's discussion, see p. 2555.

Fourth.—It is subject to unstable conditions of the vibrating water column, to an extent which renders an exact prediction of its behavior, if not impossible, at least far more difficult than that of the differential type.

The differential surge tank consists of a stand-pipe of about the same diameter as the conduit, freely connected to it, and a storage tank of larger dimensions, surrounding the stand-pipe and connected to the conduit by a properly restricted passage.

In a simple tank, the level of the stored water, following a demand for more power, represents the accelerating level which is urging more water from the forebay, and measures the head acting on the water-wheel. In the differential type, owing to the resistance interposed between tank and conduit, the level of the stored water is quite independent of the acceleration, and does not affect the water-wheel governor directly. The water in the stand-pipe takes care of these things, and acts like a simple tank of small dimension which is supplemented by the steadying action of the stored water, fed into the system in an independent, non-synchronous manner, meeting all demands for water without causing the unstable, pendulum-like behavior which is so characteristic of the simple surge tank.

On account of the possibility of a rigid mathematical treatment of the ideal or theoretical differential action, several interesting facts are discoverable which would probably not have been generally demonstrable by a study of the so-called simple tank, which, by the way, is anything but simple in all respects save as to the conception of its physical structure. Some of the features most noteworthy, are:

a.—The working volume of a differential surge tank, for a given velocity change and for a given degree of stability in regulation, is independent of the length of the conduit, the area decreasing as the length of conduit, and consequent height of tank, increase.

b.—The highest possible surge above forebay level following a complete shut-down, is not necessarily due to the shutting off of the maximum velocity obtainable, but may occur as a result of throwing off part load at a critical velocity.

c.—It is possible, and often quite feasible, to design for a perfect dead-beat or non-oscillatory condition, where no unnecessary

motion of the water occurs, nothing more than a change of level corresponding to the inevitable gradient change.

d.—Every design is intimately associated with an infinite number of similar designs, so related, kinematically, that the one type may be varied indefinitely in its own class, without further computation, except of a primitive nature. This fact favors graphical methods, and enables all computations to be reduced to the utmost simplicity.

These features are here brought out, along with a general mathematical treatment deduced from fundamental principles of mechanics, and the illustrations by Mr. Taylor complete the demonstration of the differential principle, and show its advantages over the ordinary method now in somewhat general use.

Introduction.

The function of a stand-pipe or simple surge tank, to regulate a long enclosed column of water feeding water-wheels, is well enough understood, and many authors have written on this subject since the presentation of the writer's paper entitled "The Surge Tank in Water Power Plants."* Therefore he will pass over the elementary matter, involving description of the undulating water wave produced by load changes, and take up the more technical side of the question, illustrating some exact mathematical methods of arriving at intelligent results in design. In the following studies the exact determinations are confined to the first quarter cycle of the water wave, that is to say, the period during which the first drop or rise of water within the tank takes place, up to the time when a reversal of motion of the water begins.

The differential surge tank or regulator, as has been described in the writer's previous paper, consists of a simple stand-pipe freely connected to the water-power conduit, and supplemented by a tank surrounding the stand-pipe and communicating with the conduit through a definitely restricted opening. This restricted passage offers a resistance to the flow of water back and forth through it, and, when properly designed and proportioned, has a remarkably beneficial effect on surges which would otherwise attain harmful, if not dangerous, proportions in a simple surge tank of much larger dimensions.

* *Transactions*, Am. Soc. Mech. Engrs., Vol. 30, p. 443 (1908).

No one has yet succeeded in writing correct equations for the phenomena during the first quarter cycle in a simple surge tank, when friction, velocity head, and governor action are considered. Neither is it possible to do this for the differential regulator, except for the case when the stand-pipe area approaches zero for a surrounding tank of a given size. A certain capacity of stand-pipe is essential for many reasons, as will appear later; one of its principal benefits is to furnish a little time for the pressure change following a load change, so as not to interfere with the governor and throw additional duty on the fly-wheel. It is highly instructive and very satisfactory to be able to write perfectly exact equations for all the phenomena which take place during the first quarter cycle, taking into account the friction in the conduit and eliminating without error the action of the governor. This can easily be done when the capacity of the internal stand-pipe approaches zero, and the subsequent addition of this capacity and the further refinement of the area of the restricted passage for an actual design become an easy task for a little judgment assisted by arithmetic integration.

An undulation or water wave once set in motion by a load change may have any one of four characteristics, depending on the size of the tank, other conditions being fixed.

(1) It may die out as a damped harmonic;

(2) It may live indefinitely at the same amplitude;

(3) It may increase in amplitude with each oscillation;

(4) It may continue to drop, theoretically, without turning around to rise again, if the acceleration of the conduit is not fast enough to catch up to the increasing draft velocity as the head recedes and the governor opens up the water-wheel wider and wider.

(This last case is interesting only from a mathematical standpoint, and will not here be further considered.)

(5) As a modification of Case (1), it may die out with no oscillation at the end of the first quarter cycle in infinite time. This case is called the non-oscillatory or dead-beat condition, where perfect or absolute damping takes place, and the water does not pass beyond the normal quiescent level due to the velocity required by the suddenly applied load.

When load changes happen to occur in step with the natural period of vibration of the water column, Case (1) usually takes on the characteristics of Case (3), and experience has shown that this test, applied to many simple tank designs, disqualifies them for safe use. On the other hand, it is extremely rare to hit upon a case where a differential regulator will not hold the water within definite limits up and down, however long synchronous load changes be applied. Under these conditions the vibration may sometimes increase for one or two swings, after which it will remain at constant amplitude for an indefinite number of continued synchronous load changes. The writer recently ran across a practical case where a simple tank of certain dimensions took on the characteristics of Case (3), following a single load change, and the same tank, converted into a suitable differential regulator, successfully withstood the test, even, of synchronous load changes. Case (5) is in most cases economically out of the question to obtain with a simple tank, but frequently for long pipe lines, large friction, or high velocities, or all of these, it becomes quite possible to design for the dead-beat condition with the differential principle.

One of the interesting paradoxes of this question is the fact that stable regulation, or freedom from vibration, becomes easier to obtain as the inertia effects get worse. In other words, a surge tank of given area will approach the dead-beat wave as the length of the pipe line and the velocity increase. The height of such a tank would have to increase with the length of the pipe line and with the velocity, but unless the area were correspondingly decreased, the oscillation would become steadier as the inertia effects became worse. The reason for this is that the work which may be accomplished within a surge tank is proportional to the square of the height through which the water may be permitted to vary, and this height, for equivalent stability, may vary directly as the friction gradient, which itself varies directly as the length of the pipe line and about as the square of the velocity. The work required to be done, however, varies only directly as the friction gradient, which is to say, also, as the length of the pipe line and as the square of the velocity. Hence, doubling either of these quantities would double the permissible height for water variation within the tank, and would thereby multiply its capacity for work by four. This brings out forcibly the important fact that

very long pipe lines need not be avoided through any misconceived fear of dangerous oscillations of the water column. The unavoidably large change in gradient following a load change is, to be sure, a somewhat undesirable attribute of a very long pipe line, because it causes the governor to travel a little farther than it would if the head did not vary, but no more serious effect than this comparatively mild one need be apprehended if the regulator is designed intelligently.

Some people have argued against the differential action because it causes a more rapid initial variation in head than the simple surge tank, but the fact is that the small capacity furnished by the internal stand-pipe of the differential regulator is quite sufficient to afford just as good practical results as a simple tank of like dimensions, and the manifest advantages in all other respects ought to make it the preferred type in all cases. The writer has never yet found a condition where he could see any advantage in the use of a simple surge tank, and long ago he abandoned the idea entirely, as always extravagant, often impracticable, and sometimes dangerous.

Another important function of the internal stand-pipe is to afford a relief overflow into the tank in case of a sudden shut down, which causes the water to rise immediately to the top of the stand-pipe, and, while spilling into the tank, the conduit receives the benefit of this suddenly applied back pressure which cuts down to a minimum the total quantity of water to be caught. For ordinary load changes, the water merely rises or falls a moderate distance within the stand-pipe, without, of course, overflowing, and the effect of the restricted opening is to force a more rapid variation of level in the stand-pipe than takes place in the surrounding tank, but the restriction is ordinarily not sufficient to cause a greater total variation of level in the stand-pipe than subsequently takes place in the tank due to the transfer of water through the restricted passage. The object of this restriction is to cause a greater acceleration than would result from the comparatively sluggish movement of the water surface in a simple tank, thereby minimizing the quantity of water to be handled by the tank and greatly increasing its ability to check or choke harmful and unnecessary surges. The size of a simple tank to produce the same net results as to regulation of the water-wheel is sometimes enormously larger than that of a differential regulator, the exact

ratio depending on the conditions to be met, and this is especially evident when the test of synchronous load changes is applied.

The ideal differential action to which the following equations apply needs a careful description in order to forestall any misconception as to the limitations of the mathematics, and to set forth clearly the general fundamental conditions which make possible at all a rigid mathematical treatment of the surge phenomena. Certain assumptions are necessary, which are not strictly adhered to in the final design but may be modified with little additional labor when the action of the regulator is fully understood.

First.—The stand-pipe area is considered to be so small that a variation in water level within it takes place in a negligible time compared to the remaining time in which complete acceleration of the water column is effected.

Second.—The restricted opening is assumed to vary in size according to certain laws, with the result that, when a sudden change in level takes place within the stand-pipe (due to a sudden load change), the water level remains absolutely stationary at the new position until complete acceleration is effected in the conduit.

Third.—The size of the tank is required to be such that the ultimate change in water level in one direction shall be exactly equal to the sudden change in the stand-pipe for the given load change under consideration.

Fourth.—The inertia of the water in the regulator itself is neglected.

Fifth.—Velocity changes only, rather than load changes, are considered, and therefore the head, H, is not involved in the theory; it enters only in an extraneous computation to convert velocity change into load change.

Sixth.—The friction in the stand-pipe, velocity head, and the weir head when spilling over the top, are neglected.

Seventh.—The kinetic energy in the flowing water is computed from the average velocity, $\frac{Q}{A}$, and is not refined to take into account the slight error introduced by reason of the non-uniform velocity existing in the cross-section of a cylinder of flowing water.

The first assumption is never actually realized, except where compressed-air tanks are used.

The second assumption is seldom, if ever, actually necessary, because, as will appear later, a constant size of choke hole is quite adequate for practical results, especially when assisted by some capacity in the stand-pipe which has to be neglected for the sake of the integral calculus.

As has been stated before, the following mathematical treatment in its entirety deals only with the phenomena which take place during the first quarter cycle of the water wave; that is to say, during the period of the first programme of acceleration, positive or negative, while the water level in the tank is changing in one direction and that in which it has been started by a load change. The subsequent plotting of the various waves of pressure and velocity must be carried on by recourse to the principles of arithmetic integration which any one who has the patience and is sufficiently interested may do with no more than an ordinary understanding of the fundamental laws of Newton and a good training in the rapid use of a slide-rule. It is not the present purpose to describe these methods in detail, because satisfactory results may be obtained in many ways, and the individual may often select the method best suited to his mind. Suffice it to say that although the mathematical treatment herein set forth is as complete as the writer has been able to make it, yet when the design of a regulator is approximated as closely as possible from the available equations, it is usually much more satisfactory and profitable to one lacking experience, to integrate the phenomena second by second in the common-sense way than to rely solely on judgment for the effect of the departures which have to be made from the hard and fast mathematical assumptions and results.

The ideal differential action to which the equations apply is necessarily confined to one particular load change, and if mathematically ideal conditions were required for a greater load change, the size of the choke hole would have to be increased. It follows, therefore, that the design should be made ample in the first place for the greatest load change for which good regulation is desired, and this should be controlled by the size of the greatest ordinary daily sudden variation when the operation of the plant is regular and normal. If there occurs a greater load change than that for which the regulator has been designed, the result will be a greater total variation of pressure level within the stand-pipe than is necessary or than subsequently takes

place in the tank, and this condition is not desirable as an ordinary operating feature. If, however, abnormal conditions obtain for a time, such as synchronous load changes or excessively large ones, this disproportionate variation in water level within the stand-pipe is an excellent thing, because it serves to counteract and deaden any tendency toward an increasing or unstable vibration of the water level. In other words, the differential action should be harmless under normal conditions, if properly designed, and should be particularly beneficial for abnormal conditions. The advantage of this principle, as distinguished from the simple tank, is not nearly so apparent during the first quarter cycle as it is later in the history of the wave, but even at first it has one decided advantage in that the total variation of head on the wheel is considerably less than in a simple tank of equal size; this permits a smaller water-wheel to adhere to the load following a load change without reaching full gate, or conversely, permits a wheel of the same size to deliver the new increased load at smaller gateage, which means at better efficiency if near full gate, and which, therefore, means less acceleration required in the long conduit, and better conditions all around.

Proper characteristics of the water-wheel itself are of great importance in assisting the surge tank, and particular attention should be paid to the water-wheel specifications, if the surge tank is not to be unreasonably taxed; and, if the wheels are already installed when the task of providing a suitable regulator is undertaken, a knowledge of the water-wheel characteristics is essential for intelligent design. While the efficiency is increasing with the load, regulation is comparatively easy, but, beyond the crest of the efficiency curve, the regulator has additional work to do, and in some instances of excessive friction in a long conduit, further opening of the gates may actually produce less power, which is a case impossible for any regulator to improve.

Nomenclature.—The nomenclature herein adopted is as follows:

t = time in general;
t_a = time of acceleration;
t_r = time of retardation;
T = time to complete one quarter cycle of the water wave;
L = length of the conduit;
A = area of the conduit;

F = net area of tank, that is, in excess of the stand-pipe area;

a = area of restricted opening or port with 100% coefficient of discharge;

a_0 = area of restricted opening when $t = 0$;

a_1 = area of restricted opening when $t = T$;

v = velocity in the conduit;

v_1 = initial conduit velocity before acceleration begins ($t_a = 0$), or = conduit velocity when $t_r = T$, or = constant-draft velocity between surge tank and water-wheel, in terms of the conduit velocity during retardation;

v_2 = conduit velocity when $t_a = T$, or = initial conduit velocity before retardation begins ($t_r = 0$), or = constant-draft velocity between surge tank and water-wheel in terms of the conduit velocity during acceleration;

c = a coefficient such that cv^2 = total losses of head in the conduit (these losses may or may not include the velocity head, depending on the location of the surge tank);

y = departure of the water level in the tank from its initial quiescent position previous to a load change;

$y_1 = y$ for $t = T$ = also, by hypothesis, the amount of the initial sudden change of level in the stand-pipe;

p = percentage of velocity change = $\frac{v_2 - v_1}{v_2}$ in acceleration;

$r = \frac{v_1}{v_2} = 1 - p$;

k = stability factor of the water wave = $\frac{y_1}{c\,(v_2^2 - v_1^2)}$;

log. = natural logarithm, where not specified;

$$Z = \sqrt{\frac{y_1}{c} + v_1^2}, \text{ or } y_{1_a} = c\,(Z^2 - v_1^2);$$

$$Z_1 = \sqrt{v_2^2 - \frac{y_1}{c}}, \text{ or } y_{1_r} = c\,(v_2^2 - Z_1^2);$$

$$Z_0 = \sqrt{\frac{y_1}{c} - v_2^2}, \text{ or } y_{1_r} = c\,(v_2^2 + Z_0^2);$$

$$X = \frac{Z}{v_2} = \sqrt{k\,(1 - r^2) + r^2}.$$

ACCELERATION.

By hypothesis we have, for positive acceleration,

$$dt = \frac{\frac{L}{g}\, d\, v}{y_1 - c\,(v^2 - v_1^2)}$$

from which, by integration between the limits v_1 and v, we have the general expression for the time which has elapsed in acquiring any velocity

$$t_a = \frac{L}{2\,g\,c\,Z} \log. \frac{(Z - v_1)\,(Z + v)}{(Z + v_1)\,(Z - v)} \quad \ldots\ldots\ldots\ldots\ldots (1)$$

Multiplying both sides of the differential equation by $A\ v$, we have

$$A \int_0^t v\, dt = \frac{A\ L}{g} \int_{v_1}^{v} \frac{v\, dv}{y_1 - c\,(v^2 - v_1^2)},$$

which equals the total quantity of water discharged through the conduit in the time, t. Now, by hypothesis, the total quantity drawn through the water-wheels in the time, t, is $A\ v_2\ t$, and the difference must be taken from the tank; whence,

$$A\ v_2\ t_a - \frac{A\ L}{g} \int_{v_1}^{v} \frac{v\, dv}{y_1 - c\,(v^2 - v_1^2)} = y\, F.$$

Integrating and simplifying, and substituting the value of t_a from Equation (1), we have

$$y = \frac{A\ L}{2\,g\,c\,F} \left\{ \frac{v_2}{Z} \log. \frac{(Z - v_1)\,(Z + v)}{(Z + v_1)\,(Z - v)} - \log. \frac{Z^2 - v_1^2}{Z^2 - v^2} \right\} \ldots (2)$$

This is the general expression giving the momentary relation between the drop in water level in the tank and the corresponding conduit velocity which has been attained.

When v becomes equal to v_2, y becomes equal to y_1, if F is of the correct size, hence we may place $y = y_1$, and solve for F. Remembering that

$$T_a = \frac{L}{2\,g\,c\,Z} \log. \frac{(Z - v_1)\,(Z + v_2)}{(Z + v_1)\,(Z - v_2)} \quad \ldots\ldots\ldots\ldots\ldots (3)$$

we have, for correct size of tank,

$$F = \frac{A\ L}{2\,g\,c\,y_1} \left\{ \frac{v_2}{Z} \log. \frac{(Z - v_1)\,(Z + v_2)}{(Z + v_1)\,(Z - v_2)} - \log. \frac{Z^2 - v_1^2}{Z^2 - v_2^2} \right\} \ldots (4)$$

or, in other notation,

$$F = \frac{A\ L}{2\,g\,c^2\,v_2^2\,k\,(1 - r^2)} \left\{ \frac{1}{X} \log. \frac{(X - r)\,(X + 1)}{(X + r)\,(X - 1)} - \log. \frac{k}{k - 1} \right\} (5)$$

from which F may be solved directly for any velocity change and any degree of stability, k, desired. Equation (5), at first sight, may seem to be a useless algebraic contortion of Equation (4), but it may be found instructive to have due regard to k rather than the more direct value y_1 which in itself gives no adequate idea of how much the motion of the water level exceeds the gradient change.

The head, h_p, acting on the restricted passage or "port" at any time $= y_1 - y$, and may be expressed in terms of the corresponding velocity as follows:

$$y_1 - \frac{A\,L}{2\,g\,c\,F}\left\{\frac{v_2}{Z}\log.\frac{(Z-v_1)(Z+v)}{(Z+v_1)(Z-v)} - \log.\frac{Z^2-v_1^2}{Z^2-v^2}\right\}$$

or, substituting the value of y_1 in terms of Z from Equation (4), we have

$$h_p = \frac{A\,L}{2\,g\,c\,F}\left\{\frac{v_2}{Z}\log.\frac{(Z-v)(Z+v_2)}{(Z+v)(Z-v_2)} - \log.\frac{Z^2-v^2}{Z^2-v_2^2}\right\} \quad \ldots(6)$$

The quantity of water necessary to be forced through the port by the head, h_p, is $A\,(v_2 - v)$; therefore,

$$a\,\sqrt{2\,g\,h_p} = A\,(v_2 - v)$$

and

$$a = \frac{\sqrt{A}\,(v_2-v)}{\sqrt{\frac{L}{c\,F}\left\{\frac{v_2}{Z}\log.\frac{(Z-v)(Z+v_2)}{(Z+v)(Z-v_2)} - \log.\frac{Z^2-v^2}{Z^2-v_2^2}\right\}}} \quad \ldots(7)$$

which is the general expression for the size of the port for any assigned conduit velocity, during a surge.

When $v = v_1$ at the beginning of the cycle,

$$a_0 = \frac{A\,(v_2-v_1)}{\sqrt{2\,g\,y_1}} \quad \ldots\ldots\ldots\ldots\ldots\ldots(8)$$

When $v = v_2$, the expression becomes indeterminate, but when evaluated by differentiating the numerator and denominator, we find

$$a_1 = \left\{\frac{A\,F\,y_1}{L}\left(1-\frac{1}{k}\right)\right\}^{\frac{1}{2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots(9)$$

which is always less than a_0.

It is interesting to note the extreme simplicity of the foregoing equations when there is considered to be no friction in the conduit. A single port of fixed area is then found to be exactly adequate to hold the accelerating water level at one point while the conduit velocity

is attaining a value which satisfies the new load. In other words, when the tank has the correct area, F, the pressure head on the fixed port which exists at any instant is just that required to force through it the difference between the quantity of water demanded by the water-wheel and that being furnished, at that particular instant, by the conduit.

By hypothesis, we have

$$dt = \frac{L}{g\,y_1}\,dv \text{ and } dy = \frac{A}{F}\,(v_2 - v)\,dt.$$

Eliminating dt, we have

$$dy = \frac{A\,L}{F\,g\,y_1}\,(v_2 - v)\,dv,$$

from which, by integration between the limits v_1 and v, we obtain

$$y = \frac{A\,L}{2\,g\,F\,y_1}\left\{(v_2 - v_1)^2 - (v_2 - v)^2\right\} \ldots\ldots\ldots\ldots (10)$$

also, similarly,

$$t = \frac{L}{g\,y_1}\,(v - v_1) \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

$$y_1 = \frac{A\,L}{2\,g\,F\,y_1}\,(v_2 - v_1)^2 \text{ and } T = \frac{L}{g\,y_1}\,(v_2 - v_1) = \sqrt{\frac{2\,L\,F}{g\,A}}$$

$$F = \frac{A\,L}{2\,g\,y_1^2}\,(v_2 - v_1)^2.$$

These equations hold good for both acceleration and retardation. Expressing the area of port in terms of v and y we have, as before,

$$a^2 = \frac{A^2\,(v_2 - v)^2}{2\,g\,(y_1 - y)},$$

or, substituting the values of y_1, and y in terms of v,

$$a^2 = \frac{A\,F\,y_1\,(v_2 - v)^2}{L\left\{(v_2 - v_1)^2 - (v_2 - v_1)^2 + (v_2 - v)^2\right\}} = \frac{A\,F\,y_1}{L} = \text{constant},$$

or,

$$a = \sqrt{\frac{A\,F\,y_1}{L}} = \text{constant}. \ldots\ldots\ldots\ldots\ldots (12)$$

Equation (12) is the limit of Equation (7) as c approaches zero.

The value of a_0 for $c = 0$ may also be shown to be the same, by substituting for $(v_2 - v_1)$ in Equation (8) its value as just determined in terms of y_1, and we again have

$$a_0 = \sqrt{\frac{A\,F\,y_1}{L}}.$$

Also, since $\frac{1}{k}$ becomes zero, Equation (9) becomes

$$a_1 = \sqrt{\frac{A\,F\,y_1}{L}}.$$

The port area remains constant throughout the quarter cycle.

Equations (10), (11), and (12) are useful when c is so small as to make the previous formulas too sensitive to solve with ordinary logarithmic tables. Equation (12), as compared with Equation (7), shows that the less the friction the less the variation in a in order to hold a perfectly stationary accelerating water level in the stand-pipe. This variation in the size of effective port may be approximated as closely as desired by a series of holes up and down the stand-pipe, which would shut off automatically as the water dropped below them in the tank, but this refinement is ordinarily not warranted, and when there is some appreciable capacity in the stand-pipe, as for example, if it has an area $= A$, a single port of fixed size is quite sufficient for all practical purposes except for very unusual conditions. No serious error would be made in fixing the size of the port by Equation (8), but a trial computation by arithmetic integration for any particular case would show that a somewhat smaller hole than a_0 gives slightly better results. The reason it is not usually necessary to refine too carefully the dimensions of the port, is that, if one uses Equation (8), the port will always be somewhat too large, which is the same thing as saying that a somewhat larger velocity change than the one assumed would most nearly approach the mathematical ideal. No particular harm results from making the hole a little too large, although it should be as nearly right as possible, for as it gets larger the dangers of the simple tank are being approached.

When k approaches unity, Case (5), or the dead-beat wave, is approximated, and for $k = 1$, the water level does not pass beyond the final quiescent position for the increased load.

When $k = 1$, $Z = v_2$, and Equation (1) becomes for dead-beat conditions,

$$t_a = \frac{L}{2\,g\,c\,v_2} \log. \frac{(v_2 - v_1)\,(v_2 + v)}{(v_2 + v_1)\,(v_2 - v)} \qquad \ldots\ldots\ldots\ldots (13)$$

and when $v = v_2$, $T_a = \infty$.

Equation (2) is much simplified by substitution of $Z = v_2$ and combining the logarithms, and becomes, for dead-beat conditions,

$$y = \frac{A\,L}{g\,c\,F} \log. \frac{v_2 + v}{v_2 + v_1} \qquad \ldots\ldots\ldots\ldots\ldots (14)$$

and when $v = v_2$ and y becomes y_1, we have

$$y_1 = \frac{A\,L}{g\,c\,F} \log. \frac{2\,v_2}{v_2 + v_1} = c\,(v_2^2 - v_1^2)$$

from which

$$F_a = \frac{A\,L}{g\,c^2\,(v_2^2 - v_1^2)} \log. \frac{2\,v_2}{v_2 + v_1} \quad \ldots\ldots\ldots\ldots (15)$$

Also, when $k = 1$, $Z = v_2$ and Equation (7) becomes, for dead-beat conditions,

$$a = \frac{\sqrt{A}\,(v_2 - v)}{\sqrt{\frac{2\,L}{F\,c} \log. \frac{2\,v_2}{v_2 + v}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

Equation (8) remains unchanged, except for the possible substitution of $y_1 = c\,(v_2^2 - v_1^2)$; and Equation (9) becomes $a_1 = 0$.

It has been pointed out previously that the extent of the variation in a depends on the amount of the friction, and the greatest variation from a_0 to a_1 is found when $a_1 = 0$, for the condition of perfect damping effect. If this ideal result were required to be practically obtained with a tank as small as given by Equation (15), the standpipe would need to contain an infinite number of holes, which would merge into a slot of peculiar shape, but this is an unnecessary amount of refinement because absolute damping is very little better than a near approach to it, and, besides, a moderately larger tank could be made to accomplish it with far less refinement of the port area. One fixed hole should usually be sufficient in all cases.

The limiting value of F for small load changes is interesting, particularly because as v_2 approaches v_1 in value, the solution of previous equations becomes troublesome, and, for the complete plotting of a curve, for example, the limit must be known. It might appear at first thought that when the velocity change is zero the tank area would also be zero, but for a given required stability, k, the value of F approaches a perfectly definite limit as r approaches unity. The value of a, however, does approach zero. The limit of $\frac{(X - r)\,(X + 1)}{(X + r)\,(X - 1)}$, as r approaches unity, is $\frac{k}{k - 1}$; therefore Equation (5) is a true indeterminate with respect to F, and by multiplying numerator and denominator by X and performing the necessary successive differentiations we find

$$F_0 = \frac{A\,L}{4\,g\,c^2\,v^2\,k} \left\{ 1 - (k - 1) \log. \frac{k}{k - 1} \right\} \quad \ldots\ldots\ldots (17)$$

The value of F_0 for dead-beat conditions is also useful to assist in solving equations which approach the indeterminate form as k approaches unity.

The limit of $(k-1)\log.\frac{k}{k-1}$ as k approaches unity is zero, and therefore

$$F_{d_0}=\frac{A\,L}{4\,g\,c^2\,v^2}\qquad\ldots\ldots(18)$$

This completes the study for positive acceleration, so far as the writer has carried it up to the present time, and the variations which occur for retardation will now be considered.

Retardation.

By hypothesis, we have for retardation

$$dt=\frac{\frac{L}{g}\,dv}{y_1-c\,(v_2^2-v^2)}.$$

In the corresponding equation for acceleration the constant term in the denominator was always positive and hence the integration took but one form. In this case, however, y_1 does not always reach forebay level for part load rejected, and therefore may have a value either greater or less than cv_2^2, thus causing the constant term in the denominator to vary through zero from negative to positive as y_1 is increased.

(*1*) *When Water Does Not Reach Forebay Level on Rejection of Load.*—When $y_1 < c\,v_2^2$, we have, as for Equation (1),

$$t_r=\frac{L}{2\,g\,c\,Z_1}\log.\frac{(v_2-Z_1)\,(v+Z_1)}{(v_2+Z_1)\,(v-Z_1)}\qquad\ldots\ldots(19)$$

and, as a companion of Equation (2), we have, similarly,

$$y_r=\frac{A\,L}{2\,g\,c\,F}\left\{\log.\frac{v_2^2-Z_1^2}{v^2-Z_1^2}-\frac{v_1}{Z_1}\log.\frac{(v_2-Z_1)\,(v+Z_1)}{(v_2+Z_1)\,(v-Z_1)}\right\}\ldots(20)$$

and for the value of F we have

$$F=\frac{A\,L}{2\,g\,c\,y_{1r}}\left\{\log.\frac{v_2^2-Z_1^2}{v_1^2-Z_1^2}-\frac{v_1}{Z_1}\log.\frac{(v_2-Z_1)\,(v_1+Z_1)}{(v_2+Z_1)\,(v_1-Z_1)}\right\}.(21)$$

For the case when $y_1=cv_2^2$, which means that a certain critical value of F just forces the water to forebay level for an assigned value

of $v_2 - v_1$, we find that Equation (19) becomes indeterminate as Z_1 approaches zero. On evaluation by differentiation we have

$$t_r \text{ (for } Z_1 = 0) = \frac{L}{g\ c} \times \frac{v_2 - v}{v\ v_2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (22)$$

and Equation (20) becomes

$$y \text{ (for } Z_1 = 0) = \frac{A\ L}{g\ c\ F} \left\{ \log. \frac{v_2}{v} - v_1 \frac{v_2 - v}{v\ v_2} \right\} \quad \ldots\ldots\ldots (23)$$

$$\text{and } F \text{ (for } Z_1 = 0) = \frac{A\ L}{g\ c^2\ v_2^2} \left\{ \log. \frac{v_2}{v_1} - \frac{v_2 - v_1}{v_2} \right\} \quad \ldots\ldots\ldots (24)$$

When c approaches zero, the equations for retardation are exactly the same as already derived for acceleration, namely, Equations (10), (11), and (12).

The foregoing equations for retardation are chiefly interesting from a mathematical standpoint because in a practical case very little attention need be paid to what happens when part load is rejected, so long as a complete shut-down is properly taken care of. Therefore, the size of the port is controlled by the acceleration studies, and is limited in size only by the shut-down conditions, as will appear later. The equations for dead-beat conditions in retardation may as well be written, for the sake of comparison with Equations (14) and (15). By processes strictly analogous to the previous cases, we have for dead-beat retardation, which can exist only for rational values of $Z_1 = v_1$

$$y = \frac{A\ L}{g\ c\ F} \log. \frac{v_2 + v_1}{v_1 + v} \quad \ldots\ldots\ldots\ldots\ldots\ldots (25)$$

and when $v = v_1$ and y becomes y_1, we have as compared to Equation (15)

$$F = \frac{A\ L}{g\ c^2\ (v_2^2 - v_1^2)} \log. \frac{v_2 + v_1}{2\ v_1} \quad \ldots\ldots\ldots\ldots\ldots (26)$$

It will now be seen that F in Equation (26) is always larger than F in Equation (15), because $\frac{v_2 + v_1}{2\ v_1} > \frac{2\ v_2}{v_2 + v_1}$, and, although full load may be thrown on without producing oscillation, in which case $\frac{2\ v_2}{v_2 + v_1}$ becomes $= 2$ for $v_1 = 0$, yet oscillation is bound to occur for full load rejected, except for an infinite value of F, because $\frac{v_2 + v_1}{2\ v_1}$ becomes ∞ for $v_1 = 0$.

In other words, the water must in all cases reach a level higher than the forebay. The value of F for dead-beat conditions for very small load changes, however, would be identical with that given by Equation (18), because the limit of log. $\frac{v_2 + v_1}{2 v_1} \div (v_2^2 - v_1^2)$ as v_2 becomes $= v_1$, is $\frac{1}{4 v_1^2}$.

When Water Rises Above Forebay on Rejection of Load.—The phenomena resulting from irrational values of Z_1 will now be taken up. This is by far the more usual case in practice, where the water rises above forebay level following a rejection of part load. As Z_1 becomes a surd, it is no longer of any use, and it must be supplanted by $Z_0 = \sqrt{\frac{y_1}{c} - v_2^2}$. Reverting to the original differential equation,

$$dt = \frac{\frac{L}{g} d v}{y_1 - c (v_2^2 - v^2)}$$

we find that when $y_1 > c v_2^2$, the integration takes the form of the tan.$^{-1}$, instead of the log., and we have

$$t_r = \frac{L}{g c Z_0} \left\{ \text{tan.}^{-1} \frac{v_2}{Z_0} - \text{tan.}^{-1} \frac{v}{Z_0} \right\} \ldots\ldots\ldots\ldots (27)$$

and

$$y = \frac{A L}{2 g c F} \left\{ \text{log.} \frac{v_2^2 + Z_0^2}{v^2 + Z_0^2} - \frac{2 v_1}{Z_0} \left(\text{tan.}^{-1} \frac{v_2}{Z_0} - \text{tan.}^{-1} \frac{v}{Z_0} \right) \right\} (28)$$

and

$$F = \frac{A L}{2 g c y_1} \left\{ \text{log.} \frac{v_2^2 + Z_0^2}{v_1^2 + Z_0^2} - \frac{2 v_1}{Z_0} \left(\text{tan.}^{-1} \frac{v_2}{Z_0} - \text{tan.}^{-1} \frac{v_1}{Z_0} \right) \right\} (29)$$

and evaluating Equation (29) for $Z_0 = 0$ we again have Equation (24), which shows that Equations (29) and (21) draw together, as they should, and become identical for the condition that forebay level shall exist in the tank when $t_r = T_r$.

The most useful equations for rejected load are those pertaining to a shut-down when $v_1 = 0$, and Equation (28) becomes

$$y = \frac{A L}{2 g c F} \text{log.} \frac{v_2^2 + Z_0^2}{v^2 + Z_0^2} \ldots\ldots\ldots\ldots\ldots (30)$$

and Equation (29) becomes

$$F = \frac{A L}{2 g c y_1} \text{log.} \frac{v_2^2 + Z_0^2}{Z_0^2} \ldots\ldots\ldots\ldots\ldots (31)$$

and, as $k_r = \frac{y_1}{c\, v_2^2}$, we may rewrite Equation (31) in terms of k_r as follows:

$$F = \frac{A\, L}{2\, g\, c^2\, v_2^2\, k_r} \log. \frac{k_r}{k_r - 1} \quad \ldots\ldots\ldots\ldots\ldots\ldots (32)$$

from which k_r may be determined by trial, provided F has been previously fixed by the consideration of demanded load. It sometimes happens, however, that F is fixed by the maximum hydrostatic pressure desirable which determines k_r, in which case the value of a for demanded load is subject to adjustment to a given value of F.

The limiting size of the port hole, a_1, for a shut-down which obtains when $t_r = T_r$, just as the water comes to rest in its upward movement in the tank at the level of the top of the stand-pipe, is determined by processes analogous to those used in arriving at Equation (9) and becomes

$$a_1 = \left\{ \frac{A\, F\, y_1}{L} \left(1 - \frac{1}{k_r}\right) \right\}^{\frac{1}{2}}$$

or,

$$a_1 = v_2 \left\{ \frac{A\, F\, c}{L} (k_r - 1) \right\}^{\frac{1}{2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (33)$$

If k_r has been determined by trial from Equation (32), its value may be substituted in Equation (33) and the limiting value of a derived. The size of the port hole, as determined for demanded load, must not exceed this limiting value, for otherwise the water, having reached the top of the stand-pipe, following a shut-down, will not remain there for the time, T, but will shrink back down the stand-pipe during the quarter cycle, afterward rising again, and thus will produce a condition contrary to the hypothesis of a constant value of y_1, and may introduce an error of some magnitude. It happens, fortunately, that the requirement of design for excessively large demanded loads is rare, and almost always, when the value of a is decided on for demanded loads, it is incidentally smaller than the limiting value given by Equation (33). This will always be the case when, in the acceleration studies, $2\, r$ is not less than

$$c\, v_2 \sqrt{\frac{2\, g\, F}{A\, L}} + \frac{1}{10} \quad \ldots\ldots\ldots\ldots\ldots\ldots (34)$$

which has been determined by graphical methods, but should be verified by trial for any particular case. It will be observed that the less the friction, other things remaining unchanged, the greater the load change

for which the capacity of the port will provide without exceeding a suitable size for a shut-down; and when $c = 0$, the same value of a would be suitable, either for throwing on or off the full load. The factor, $\frac{1}{10}$, in Equation (34) is merely empirical.

In selecting the value of v_2, to determine the maximum height of the tank, it must be borne in mind that a larger value is likely to be required than the value of v_2 found for a maximum load demanded, because the conduit velocity somewhat exceeds the value existing when $t_a = T$, except for dead-beat conditions, and a shut-down could occur just at the critical point of maximum conduit velocity during the second quarter cycle following an increment of load. The extent of this excess may be left to the judgment, or it may easily be roughly determined by a few steps of arithmetic integration. It is really so small a matter as compared to the uncertainty attending the selection of a low enough value of c, that the judgment is usually quite sufficient, and, furthermore, it does not always follow that higher velocities call for higher surge tanks to catch all the water, for, as will now be demonstrated, there exists for all conditions, except the hypothetical one where $c = 0$, a critical velocity which necessitates a higher surge tank than any greater or smaller velocity. This critical velocity, of course, may be greater than that due to full load, but it frequently occurs at part load for large values of c or L, and in general for values of k_a near unity.

The height above forebay level to which the stand-pipe and tank must be carried to provide sufficient capacity to catch all the energized water following a shut-down, let us call d, and its value is evidently

$$d = c\ Z_0^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (35)$$

and it is required to find the value of v_2 which makes d a maximum; and as c is constant for any particular case, d will be a maximum when Z_0 is a maximum.

Putting $y_1 = c\ (Z_0^2 + v_2^2)$ in Equation (31), we have

$$\frac{2\,g\,c^2\,F}{A\,L} = \frac{\text{log. } (v_2^2 + Z_0^2) - 2 \text{ log. } Z_0}{Z_0^2 + v_2^2}$$

from which we may find the value of v_2 when $\frac{d\,Z_0}{d\,v_2} = 0$, which we shall call v_c, and we have

$$v_c = \frac{1}{c}\left\{\frac{A\,L\,(e-1)}{2\,g\,F\,e}\right\}^{\frac{1}{2}} \ldots\ldots\ldots\ldots\ldots\ldots (36)$$

in which e is the base of the natural logarithms and v_c becomes a little less than

$$\frac{1}{10\,c}\sqrt{\frac{A\,L}{F}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (37)$$

If the value of v_2 which is chosen as a maximum to determine the greatest height of tank and stand-pipe is greater than v_c, we must conclude that a shut-down from some part load will require a higher elevation to avoid spilling. In many cases v_c may not be so much above v_2 as materially to increase the height of tank if the former value is assumed, even though we do not expect quite so high a value, and, where economically feasible, it is best to provide for the worst case chiefly because the absolute maximum velocity which may at some future time exist coincident with a shut-down is a difficult thing to fix with precision. It is usually economically feasible to do this when the value of c is high, as is commonly the case for very long pipe lines. When not commercially desirable to do this, the value of $\frac{v_2}{c}$ must be made large enough to cover all reasonable contingencies. The value of d for $v_2 = v_c$ may be expressed by solving for $d = c\,Z_0^2$ in Equation (31) and we have

$$d_{max.} = \frac{A\,L}{2\,g\,c\,e\,F} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (38)$$

which is the greatest distance above forebay level which a tank of area F need ever be carried for any velocity whatsoever. Perhaps the most striking feature of this equation is its independence of the value of L. This is evident because c is proportional to L. The limiting value of a_1 for v_c is obtained from Equations (33), (36), and (38), namely,

$$a_1 \text{ (for } v_c) = \frac{A}{\sqrt{2\,g\,c\,e}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (39)$$

Equation (33) may also be written

$$a_1 = \sqrt{\frac{A\,F\,d}{L}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (40)$$

This concludes the study in its present state of development, and it is to be hoped the critics will add something to it. Before closing it is desired to call attention to the kinematic relation which ties together all the foregoing equations.

For a given value of p and k in Equation (5), the number represented by $\frac{2\,g\,c^2\,v_2^2\,F}{A\,L}$ is constant $= N^2$ (say).....(41)

That is, if a certain fixed percentage velocity change, p, is desired together with an assigned fixed degree of stability, k, then any mutual interchange in the values of Equation (41) may be made without affecting the result. This is very important because each assignment of p and k covers an infinite variety of combinations without further computation except to manipulate Equation (41) in any conceivable manner so long as the ratio there expressed remains constant. As c varies approximately as $\frac{L^*}{A^{\frac{3}{5}}}$, we may more properly write, in this connection, $c = \frac{f\,L}{A^{\frac{3}{5}}}$ where f is the coefficient of friction, and Equation (41) becomes, omitting the constants, 2 g and f,

$$\frac{v_2^2\,L\,F}{A^{2.2}} = \text{constant.}$$

Also, similarly, $\frac{a\,\sqrt{L}}{A^{1.3}} = \text{constant}$, as $\frac{a\,\sqrt{c}}{A}$ is constant in Equations (8), (9), etc., for fixed values of p and k.

L and F may be varied inversely with respect to each other, v and A remaining constant, or any other similar interchange may be made without affecting the kinematic relation of the design to the assigned requirements.

As $L\,v^2$ is a measure of energy, it is apparent that the area of the surge tank varies inversely as the energy in the water column, other conditions remaining unchanged. If a design were contemplated where the values were as follows:

$$v_2 = 5,\ L = 5\,000,\ F = 1\,600,\ A = 100, \text{ and } a = 10,$$

a model on a small scale might be made which would give a good idea of the adequacy of the design, if the following values were used, keeping the total ratio $= 7\,962$ and 1.776 respectively,

$$v_2 = 2,\ L = 500,\ F = 10,\ A = 1.52, \text{ and } a = 0.137.$$

*This expression for the variation of c is not intended to represent an accepted law; it is merely illustrative. According to Williams and Hazen, for example, c would vary as $\frac{L}{A^{0.584} \times v^{0.15}}$, and some such suitable refinement would be desirable for actual use.

FIG. 1.

This interesting relation of scale suggests a convenient method of treating the entire subject graphically and thus avoiding all trial and error computations, involving cumbersome logarithms and anti-tangent functions, and enabling determinations to be easily made where the equations become sensitive as they approach indeterminate forms. The writer uses graphical methods almost entirely, where all the possible

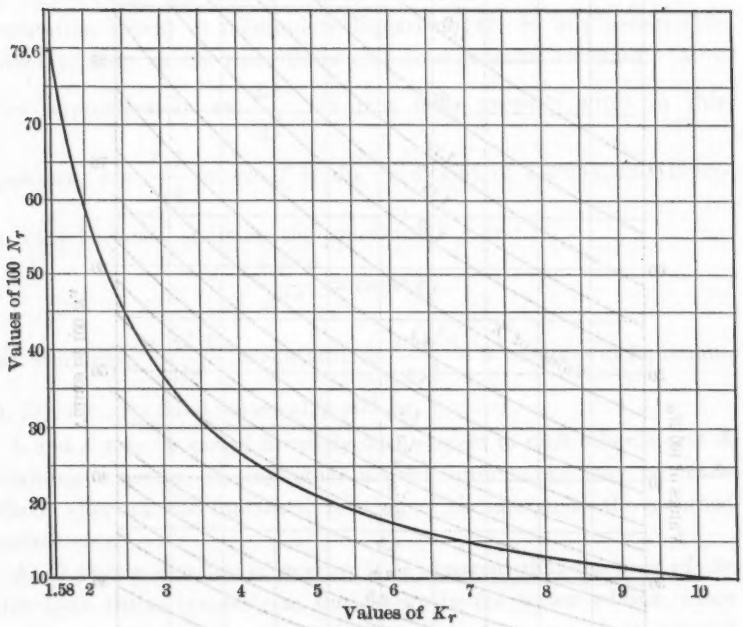

FIG. 2.

combinations are computed once for all. As N (in Equation 41) need never be larger than the value which provides non-oscillatory conditions for full load thrown on, its maximum value may be determined from Equation (15) when $v_1 = 0$. This is found to be

$$N_a \text{ max.} = \sqrt{2 \log. 2} = 1.178 \ldots\ldots\ldots\ldots\ldots (42)$$

Thus it is seen that the value of N in acceleration does not vary through a wide range, and all possible values may easily be contained on one sheet of cross-section paper, for they all lie between 0 and 1.178.

Similarly, for a shut-down, the value of N_r max. may be obtained from Equation (36) in which

$$N_r \text{ max.} = \sqrt{\frac{e-1}{e}} = 0.796 \ldots\ldots\ldots\ldots\ldots (43)$$

and all the possible values of N_r lie between zero and 0.796, and may also easily be completely contained on a single sheet of cross-section paper. The most convenient method is to plot 100 N_a as ordinates with 100 p as abscissas for each assigned value of k_a (Fig. 1). Also, for the shut-down chart, it is quite convenient to plot one curve, expressing the relation between N_r and k_r (Fig. 2).

In closing, the writer wishes to emphasize the necessity of performing the computations for numerous cases by the tedious process of arithmetic integration in order to become familiar with the uses and limitations of the foregoing equations. Since, with one fixed value of a, the water level in the stand-pipe cannot be made to hold exactly constant, it follows that the head, H, and the action of the governor have some influence on the results, very little for small values of N and increasing as $\frac{N}{H}$ increases, but seldom, if ever, leading to serious errors in a practical case.

PENSTOCK AND SURGE-TANK PROBLEMS.

By Minton M. Warren, Esq.

To be Presented December 2d, 1914.

Synopsis.

Object.—The object of this paper is to give, in their best form, formulas for solving certain penstock and surge-tank problems, and to derive them from the fundamental principles on which they rest. In the case of ordinary water-hammer, for instance, for which every pipe should be investigated, there is no literature in English except certain incomplete translations from the Italian and Russian. Most of the formulas given in standard books are either limited in their application, incorrect, or contain typographical errors, making them useless. Their results differ by 100 per cent. It is with the object of clearing up such errors that this paper is presented.

Digest of Paper.—The paper may be classified under three headings:

Water-Hammer;
Surge in Surge Tanks; and
Economical Penstock Size.

Under the heading, "Water-Hammer", the ordinary formula for maximum water-hammer is first derived. A simple formula for ordinary cases, when the gate is not closed instantaneously, is then given. The formulas of other writers for this case are also derived, and

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

their limitations and inaccuracies are shown by numerical examples.

Under the heading, "Surge in Surge Tanks", a new formula is given, with a mathematical derivation which it is hoped will be readily understood and followed.

A simple formula for Economical Pipe Size is given for use in water-power developments having long pipes or penstocks.

Conclusions.—Although water-hammer and surge-tank design are common problems to the hydraulic engineer, English literature on these subjects is scattered and incomplete. From constant copying, the formulas have become wrongly applied, and for special cases they are sometimes given as general. Starting with fundamental principles, these problems can be solved by any engineer, and are less complicated than may appear at first sight.

Introduction.

The purpose of this paper is, first, to give in their simplest form for ready reference the best formulas for solving certain surge-tank and penstock problems; and second, for the benefit of engineers who do not believe a formula merely because they see it in print, completely to derive each formula from the fundamental principles on which it rests. All the corresponding formulas which have been found in current literature are then given, and finally numerical examples are worked out, with a comparison of numerical results, using all the different methods. A bibliography of the subject is appended.

Many of these formulas have been published before in standard works, but the writer has found in many cases typographical and other errors that rendered them misleading or incorrect. In most cases no derivation is given, and therefore such errors are difficult to locate.

Formula (B) for ordinary water-hammer, Formula (G)* for surge tanks, and Formula (H) for economical pipe diameter have not been presented before, as far as the writer knows. Moreover, the usual general formulas for water-hammer given in standard works all appear to be more or less limited in their application.

---

*Since the foregoing was written, a series of articles on surge tanks, by Professor Prasil, has appeared in *The Canadian Engineer*, in which the method of attack is very much the same.

The writing of this paper was prompted by the fact that, in investigating the safety of a certain pipe design against water-hammer, the formulas given by one authority showed it to be safe, and another formula indicated that the pipe thickness should be doubled. All the best literature on the subject was found to be in Italian or Russian.

On comparing the formulas from all sources, it appeared that one, Formula (*A*), on which all writers agreed, applied up to a certain critical time. Beyond this time another formula applied. At the critical time alone, both formulas held.

On testing the different formulas for this critical time, the results differed widely and were inconsistent with Formula (*A*). Some gave impossible results above the theoretical maximum; with others the results were half as large.

This showed that some of the formulas were fundamentally wrong, and for this reason a rational general formula was sought.

The following is not intended to be an exhaustive treatise on the subject of penstocks and surge tanks. Certain complications, such as governor action, are omitted altogether. The formulas are derived from the maximum values, in which the engineer is most interested, and against which he has to design. Formulas for cases in which only part load is thrown off or on are not given, as the results are less, numerically, and the complication of dealing with two velocities is considerable. In the case of starting or stopping, one of these velocities becomes zero. The mathematics has been simplified as much as possible, and all assumptions have been clearly stated.

The derivations are given, not merely for the value of the resulting formulas, but as a basis for discussion and a starting point from which other special cases can be worked out.

Nomenclature.

The following gives the meaning of every term used in the formulas. All units are given in feet, pounds, and seconds, but any other consistent system will apply equally well.

A = cross-section area of surge tank, in square feet;
a = velocity of vibration along pipe, in feet per second;
b = thickness of pipe walls, in feet;
B = cost of pipe in place, per foot of diameter per foot of length;
C = coefficient in Chezy formula for friction in pipes;

D = inside diameter of pipe, in feet;

E = modulus of elasticity of pipe material in tension, taken as 4 000 000 000 lb. per sq. ft. for steel plate (28 000 000 lb. per sq. in.);

e = 2.718 base of Napierian logarithms;

F = total feet of head lost in pipe between reservoir and standpipe with Q cu. ft. per sec. flowing;

g = acceleration of gravity = 32.2 ft. per sec. per sec.;

h = head due to water-hammer alone (in excess of static head), in feet;

i = income, in dollars per year per foot of head;

K = modulus of elasticity of water in compression, taken as 42 400 000 lb. per sq. ft. (294 000 lb. per sq. in.);

L = length of pipe, in feet;

$$m = \frac{F}{2Q}\sqrt{\frac{A\,g\,P}{L}};$$

$$m' = \frac{m}{\sqrt{1 - m^2}};$$

$$N = \left(\frac{L\,V}{g\,T\,Y}\right)^2;$$

p = percentage return on investment, including profit, depreciation, maintenance, and taxes;

P = cross-sectional area of pipe, in square feet;

Q = steady flow through pipe, in cubic feet per second; in stopping, before gate starts to close; in starting, after gate is open and equilibrium is established;

q = square root of mean square of flow through penstock, in cubic feet per second. (See discussion under Economical Penstock Size.)

S = maximum surge, up or down, in feet, measured, in starting, from reservoir level; and, in stopping, from a distance below this equal to the friction head, F;

s = distance of surge-tank level from starting point at any time, in feet;

T = time of closing of gate, in seconds;

t = time after starting to close or open gate, in seconds;

t_1 = time to reach maximum draw-down, in seconds;

τ = time for a complete cycle of oscillations in the surge tank, in seconds;

u = velocity through gate at any time, in feet per second;

V = velocity of water in pipe, in feet per second corresponding to Q;

v = velocity at any time, in feet per second;

v_0 = velocity near gate at any time, in feet per second;

W = density of water, taken as 62.4 lb. per cu. ft.;

x = distance along pipe, in feet, plus, in the direction from gate to reservoir;

Y = normal static head, in feet;

y = head, in feet, at any point at any time;

y_0 = head, in feet, on gate at any time;

$\psi(t) = \dfrac{\text{area of gate}}{\text{area of pipe}}$, at time, t.

Summary of Formulas.

Maximum Water-Hammer.—$\left(T \text{ less than } \dfrac{2L}{a}\right)$.—The maximum water-hammer which is possible in a pipe will occur with instantaneous closing, or for any closing time less than $\dfrac{2L}{a}$. For this case

$$h = \frac{aV}{g} = \frac{145\,V}{\sqrt{1 + \dfrac{KD}{Eb}}} \qquad \ldots\ldots\ldots\ldots\ldots\ldots (A)$$

$$a = \frac{4\,660}{\sqrt{1 + \dfrac{KD}{Eb}}}$$

For steel pipe these become

$$h = \frac{145\,V}{\sqrt{1 + 0.01\,\dfrac{D}{b}}}$$

$$a = \frac{4\,660}{\sqrt{1 + 0.01\,\dfrac{D}{b}}}$$

Ordinary Water-Hammer.—$\left(T \text{ greater than } \dfrac{2L}{a}\right)$.—For ordinary cases

$$h = \frac{LV}{g\left(T - \dfrac{L}{a}\right)} \qquad \ldots\ldots\ldots\ldots\ldots\ldots (B)$$

Allievi gives the following, which is applicable in slow closing, but may be incorrect for quick closing:

$$\frac{h}{Y} = \frac{N}{2} \pm \sqrt{\frac{N^2}{4} + N} \quad \ldots\ldots (C)$$

$$h = \frac{N\,Y}{2} \pm Y\sqrt{\frac{N^2}{4} + N}$$

$$N = \left(\frac{L\,V}{g\,T\,Y}\right)^2$$

Surge in Surge Tanks.—The formulas for the maximum surge in a surge tank, either in starting or stopping the plant, are as follows:

In starting, S is measured from reservoir level; in stopping, it is measured from a distance below this equal to the friction head.

Neglecting friction

$$S = Q\sqrt{\frac{L}{A\,g\,P}} \quad \ldots\ldots (D)$$

A first approximation, allowing for friction, is

$$S = F + Q\sqrt{\frac{L}{A\,g\,P}} = F\left[1 + \frac{1}{2\,m}\right] \quad \ldots\ldots (E)$$

A closer approximation, allowing for friction, is

$$S = F + \frac{Q\sqrt{\frac{L}{A\,g\,P}}}{e^{\frac{\pi}{2}m}} = F\left[1 + \frac{1}{2\,m\,e^{\frac{\pi}{2}m}}\right] \quad \ldots\ldots (F)$$

where $m = \dfrac{F}{2\,Q}\sqrt{\dfrac{A\,g\,P}{L}}$.

The most nearly accurate formula is

$$S = F\left[1 + \frac{1}{2\,me^{m'(\pi - \cos.^{-1} m)}}\right] \quad \ldots\ldots (G)$$

where $m' = \dfrac{m}{\sqrt{1 - m^2}}$.

Economical Penstock Size.—The formula for economical penstock diameter is as follows:

$$D = \sqrt[6]{\frac{3\,250\,q^2\,i}{C^2\,p\,B}} \quad \ldots\ldots (H)$$

Maximum Water-Hammer.

Derivation of Formula.—Formula (*A*) may be derived at once from the fundamental concepts of work and energy.

The maximum pressure in the pipe will occur when the moving water is brought to rest instantaneously. Any section of the pipe in which the water is moving contains a known amount of energy, and, in order to bring this water to rest, all this energy must be dissipated in some way.

With instantaneous closing, the only possible outlet for the energy is:

(1) In compressing the water in the pipe,

(2) In distending the pipe.

Writing the expression for these three forms of energy, and simplifying, Formula (*A*) is obtained in one step.

We assume that all the energy of any section, l, of the pipe goes into distending the pipe and compressing the water in that particular section. The correctness of this assumption may be shown in three ways.

First.—At the gate the first element of water is stopped instantaneously, and it is impossible for it to act on any other section of the pipe than that section; similarly, we can work up the pipe step by step.

Second.—Equation (9*A*), given later under the heading "Ordinary Water-Hammer", shows that the pressure is propagated up the pipe as a wave without loss of intensity, and, therefore, all parts of the pipe attain the same maximum pressure.

Third.—By experiment with very fast closing of gates, it has been found that the pressure rise is constant at all parts of a given pipe and for practically any length of pipe.

The energy of the moving water in a section of pipe of any length, l, is

$$\text{weight} \times \frac{\text{velocity}^2}{2g}$$

$$= \frac{W \pi D^2 l}{4} \times \frac{V^2}{2g}$$

$$= \frac{W \pi D^2 l V^2}{8g} \text{ foot-pounds} \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

The maximum pressure tending to compress the water in the pipe is

$$Wh \frac{\pi D^2}{4} \text{ (in pounds)},$$

and, as this starts at zero and increases uniformly, the average pressure is half as great.

The distance (measured along the pipe) which l feet of water will be compressed is

$$\frac{Wh\,l}{K} \text{ feet.}$$

The work done in compressing l feet of the water, therefore, is

$$\frac{Wh\ \pi D^2}{4} \times \frac{1}{2} \times \frac{Wh\,l}{K}$$

$$= \frac{W^2h^2\,\pi\,l\,D^2}{8\,K} \text{ foot-pounds.} \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

The maximum tension tending to burst a section of pipe of length, l, is

$$\frac{Wh\,l\,D}{2} \text{ pounds, maximum pressure.}$$

As this starts at zero and increases uniformly, the average tension is half of this.

The distance which the ring of steel forming the pipe will stretch is

$$\frac{Wh\,D\,l\,\pi\,D}{2\,b\,E\,l} = \frac{Wh\,\pi\,D^2}{2\,b\,E} \text{ feet.}$$

The work done in stretching this steel, therefore, is

$$\frac{Wh\,D\,l}{2} \times \frac{1}{2} \times \frac{Wh\,\pi\,D^2}{2\,b\,E}$$

$$= \frac{W^2h^2\,\pi\,l\,D^3}{8\,b\,E} \text{ foot-pounds} \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Setting the expression (1) for the energy in the pipe equal to the two expressions (2) and (3) for the work done by the water in coming to rest, we get

$$\frac{W\,\pi\,l\,D^2\,V^2}{8\,g} = \frac{W^2h^2\,\pi\,l\,D^2}{8\,K} + \frac{W^2h^2\,\pi\,l\,D^3}{8\,b\,E},$$

and simplifying

$$h^2 = \frac{V^2}{W\,g\left(\frac{1}{K} + \frac{D}{b\,E}\right)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

$$h = \sqrt{\frac{K}{W\,g}\,\frac{V^2}{\left(1 + \frac{K\,D}{E\,b}\right)}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

Inserting the numerical value of $\sqrt{\frac{K}{W\,g}}$, this becomes

$$h = \frac{145\ V}{\sqrt{1 + \frac{K\,D}{E\,b}}} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (A)$$

Inserting values for steel pipe:

$$K = 4.2 \times 10^7$$
$$E = 4.0 \times 10^9$$

this becomes

$$h = \frac{145\ V}{\sqrt{1 + 0.01\,\frac{D}{b}}} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Other Derivations.—Formula (*A*) has been derived by several other methods. One is as follows:

The velocity of a vibration along a pipe is shown to be

$$a = \sqrt{\frac{g}{W\left(\frac{1}{K} + \frac{D}{E\,b}\right)}} = \frac{4\,660}{\sqrt{1 + \frac{K\,D}{E\,b}}} \qquad \ldots\ldots\ldots\ldots\ldots (12)$$

(See Formula (12) under the heading "Ordinary Water-Hammer").

If the gate is closed instantly, the pressure will rise immediately to h at the gate, but it will take a time, $\frac{L}{a}$, before this rise has reached the upper end of the pipe, and before the last layer of water is brought to rest.

The principle of impulse and momentum is that the impulse (or force multiplied by time) of all forces acting on a collection of particles in any time is equal to the gain of momentum of the particles in that time (mass multiplied by velocity). In this case

$$-Wh\,P\,\frac{L}{a} = -\frac{W\,P\,L}{g}\,V$$

$$h = \frac{V}{g}\,a \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

Inserting the value of a from Formula (12) we get, as before,

$$h = \frac{4\,660\ V}{g\sqrt{1 + \frac{K\,D}{E\,b}}} = \frac{145\ V}{\sqrt{1 + \frac{K\,D}{E\,b}}} \qquad \ldots\ldots\ldots\ldots\ldots (A)$$

One point should be emphasized, namely, that as all the energy in the water is used in producing this maximum h, it is impossible to get a greater pressure than this. Therefore, any formula yielding greater results must be incorrect, as it violates the law of the conservation of energy.

What appears to the writer to be an incorrect use of the formula is given in one of the articles on this subject. This inserts the ordinary value of E_w for wood, and applies the formula to wood stave pipes.

If the staves are initially in compression, the term, Eb, should be replaced by $E_w\, b + E_s\, \phi$,

where E_w is the modulus of elasticity of the wood,
E_s " " " " " " " steel,
and ϕ " " cross-section of steel bands per unit of length of pipe.

If the staves are not initially in compression, the $E_w\, b$ drops out altogether. In any case, the sinking of the steel bands into the wood is neglected.

Ordinary Water-Hammer.

Derivation of Formula.—The maximum value of the water-hammer given by Formula (A) cannot occur if the reflected waves from the reservoir reach the gate before it is entirely closed. These waves return in what may be called the critical time, equal to $\frac{2\,L}{a}$, and, for cases where T is greater than $\frac{2\,L}{a}$, the maximum value will have to be less than that derived from Formula (A).

The rise of pressure with gradual closing is more difficult to determine than with instantaneous closing, but, as almost all cases come under this head, the problem is worthy of careful analysis.

When the gate is closed a slight amount, a wave is started up the pipe, and the pressure at the gate rises at once. If the gate is closed no farther, this pressure will continue constant until $T = \frac{2\,L}{a}$, at which time the reflected wave from the reservoir reaches the gate, and the pressure falls to normal. The pressure then falls below normal by an amount which would be identical with the above rise, if friction, etc., did not tend to damp out the vibrations. It then rises again, and repeats the cycle until entirely dissipated by friction.

If the gate continues closing, however, a new wave and corresponding rise of pressure will be started for each increment of the gate motion, and as long as the gate moves the pressure will continue to rise until the reflected waves interfere. It is assumed that the gate is closed in such a way that, in the absence of reflected waves,

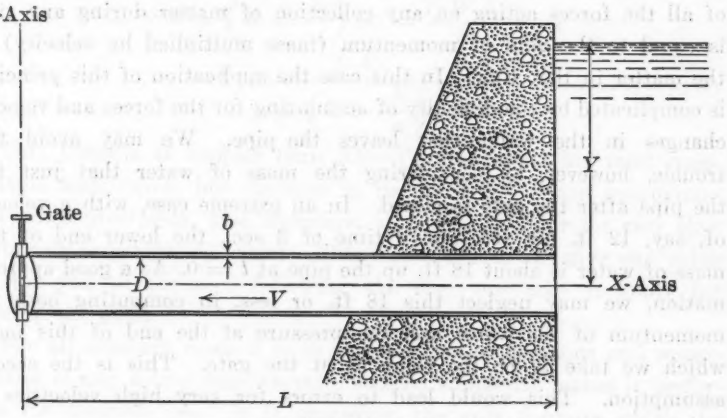

FIG. 1.

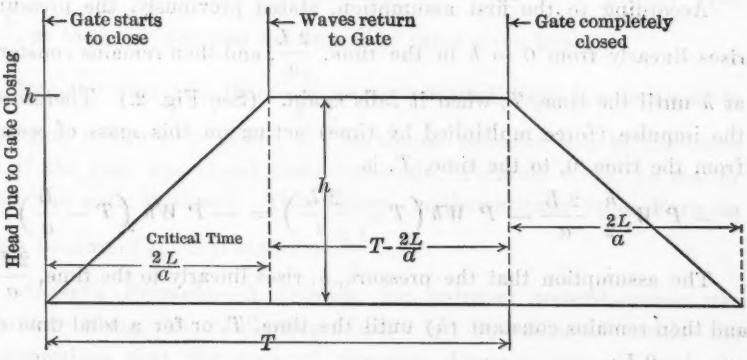

FIG. 2.

the pressure will rise at a constant rate. When the waves come back, the rate at which they are diminishing the pressure is the same as that at which the gate is increasing it. (See Fig. 2.) The pressure, therefore, will become constant until the gate is stopped, when it will begin to fall again, reaching normal after a time, $\frac{2L}{a}$. This is the

first assumption, and is very near to the truth, as experiments have shown.

In attempting to find a general formula, the principle of impulse and momentum was used. In its ordinary form, this principle is that the resultant impulse (force multiplied by time) or time integral of all the forces acting on any collection of matter during any time is equal to the gain of momentum (mass multiplied by velocity) of the matter in that time. In this case the application of this principle is complicated by the difficulty of accounting for the forces and velocity changes in the water that leaves the pipe. We may avoid this trouble, however, by considering the mass of water that just fills the pipe after the gate is closed. In an extreme case, with a velocity of, say, 12 ft. per sec. and a time of 3 sec., the lower end of this mass of water is about 18 ft. up the pipe at $t = 0$. As a good approximation, we may neglect this 18 ft. or less, in computing both the momentum of the water and the pressure at the end of this mass, which we take to be the same as at the gate. This is the second assumption. This would lead to errors for very high velocities or extremely slow closing, but not for ordinary cases.

According to the first assumption, stated previously, the pressure rises linearly from 0 to h in the time, $\frac{2L}{a}$, and then remains constant at h until the time, T, when it falls again. (See Fig. 2.) Therefore, the impulse (force multiplied by time) acting on this mass of water from the time, 0, to the time, T, is

$$-PW\frac{h}{2}\frac{2L}{a} - PWh\left(T - \frac{2L}{a}\right) = -PWh\left(T - \frac{L}{a}\right).$$

The assumption that the pressure, h, rises linearly to the time, $\frac{2L}{a}$, and then remains constant (h) until the time, T, or for a total time of $\left(T - \frac{2L}{a}\right)$, restricts the application of the formula to times greater than $\frac{2L}{a}$.

The velocity of the part in the pipe changes from V to 0*, and its

*A rigorous analysis from Allievi (given later) shows that, with the above assumptions, the velocity of the water at all points of the pipe is exactly 0 at $t = T$. This can be seen from the fact that, first, as the gate is closed, there is no velocity due to water flowing through the pipe; second, as the waves running up the pipe are exactly equal in intensity to the reflected waves coming down the pipe, there is no motion due to this cause.

mass, according to the second assumption, is $\frac{P\ W\ L}{g}$. The gain of momentum (mass multiplied by velocity), therefore, is $-\frac{P\ W\ L}{g}\ V$.

The equation of impulse and momentum, therefore, is

$$-P\ W\ h\left(T-\frac{L}{a}\right)=-\frac{P\ W\ L}{g}\ V, \text{ or}$$

$$h=\frac{L\ V}{g\left(T-\frac{L}{a}\right)} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (B)$$

This formula is simpler than Allievi's, and omits his most questionable assumption, but contains in its stead the second approximation noted previously, and, therefore, is subject to error for very slow closing or very high velocities. This formula does not give any value for the fall of pressure following the rise, nor does it apply for opening the gates.

For all ordinary cases it is as close as the assumptions and uncertainties of any actual case warrant, and its simplicity makes it preferable for common use. It is, moreover, the only formula which the writer has ever seen that is good for all values of T greater than $\frac{2\ L}{a}$, as one may see from the numerical cases given later.

For any time less than $\frac{2\ L}{a}$, as no reflected wave has returned to the gate before it is closed, the maximum pressure will be the same as if the gate was closed instantaneously (Formula (A)), no matter how the gate is closed. This follows mathematically from Formula (14) because $f\ (t) = 0$ until $t = \frac{2\ L}{a}$.

Allievi's Formula.—A formula for ordinary water-hammer was derived along the following lines by L. Allievi,* with the assumptions that the area of the gate decreases linearly and the pipe velocity decreases at a constant rate throughout its closure.† It also assumes that T is not less than $\frac{2\ L}{a}$ and is good for such values of T only. The assumption of a linear rise of pressure, which is involved in that of a linear decrease of velocity, is confirmed by actual

* *Annali* della Societa degli Ingegneri, Vol. XVII, Rome, 1902.

† These two assumptions do not seem to be exactly consistent. The second alone is assumed in deriving Formula (B), and no assumption about the gate area is made there.

experiments under different conditions and different gate motions, and the formula itself has been checked for ordinary closing of gates where T is considerably greater than $\frac{2L}{a}$.

We assume the X-axis to be parallel with the pipe along the center line, starting from the gate, and plus in the direction of the reservoir. The sense of v is opposed to this being plus in the direction from the reservoir to the gate. The pipe is assumed to be horizontal, of constant diameter and thickness, and under pressure, but the formulas hold for inclined pipes as well. (See Fig. 1.)

The first fundamental equation is that the acceleration of any thin element of water of area, P, and thickness, $d\,x$, is caused by a difference of head on its two sides.

Therefore, as mass multiplied by acceleration equals force,

$$W\,P\left(y + \frac{\delta\,y}{\delta\,x}\,d\,x\right) - W\,P\,y = \frac{P\,W\,d\,x}{g}\,\frac{\delta\,v}{\delta\,t} \quad \ldots\ldots(8)$$

$$\text{Simplifying, } \frac{\delta\,v}{\delta\,t} = g\,\frac{\delta\,y^*}{\delta\,x} \quad \ldots\ldots(9)$$

which is the first fundamental equation.

The second equation results from the fact that there is a difference of velocity at any time at different points in the pipe in consequence of the deformations due to the rise in head, $d\,y$, which causes

First.—A compression of the water;

Second.—An enlargement of section due to stretching of the steel ring of the pipe which must be filled with water.

The first part of this is

$$\frac{d\,x}{K}\,W\,\frac{\delta\,y}{\delta\,t}\,d\,t \quad \ldots\ldots(10)$$

which is the distance along the pipe in which the water is compressed.

The lengthening of the pipe ring due to y is

$$\frac{W\,y}{E} \times \frac{D}{2\,b}\,\pi\,D = \frac{\pi\,D^2\,W\,y}{2\,E\,b} \text{ (See Formula (3).)}$$

The corresponding lengthening of diameter is

$$D_1 = \frac{D^2}{2\,E\,b}\,W\,y$$

*For inclined pipes, this becomes $\frac{\delta\,v}{\delta\,t} = g\,\frac{\delta\,y}{\delta\,x} + g\,\sin.\,\alpha$, where α is the angle of inclination with the horizontal.

In a time, $d\,t$, this variation due to $d\,y$ is

$$d\,D_1 = \frac{D^2\,W}{2\,E\,b}\,\frac{\delta\,y}{\delta\,t}\,d\,t.$$

The corresponding enlargement of volume of an element of the pipe of length, $d\,x$, and area, $\frac{\pi\,D^2}{4}$, is

$$\frac{2\,\pi\,D\,d\,D_1\,\,d\,x}{4}\,; \qquad (d\,D_1 = d\,D),$$

or, inserting the above value for $d\,D_1$,

$$\frac{\pi\,D^3\,W}{4\,E\,b}\,\frac{\delta\,y}{\delta\,t}\,d\,t\,d\,x$$

Dividing the volume by the area to get the difference in the distances along the pipe which the ends of the column have moved in taking up this new volume

$$\frac{D\,W}{E\,b}\,\frac{\delta\,y}{\delta\,t}\,dt\,dx \qquad \ldots\ldots(11)$$

which is the second part required.

The difference in velocities between any two points of the pipe is due to the sum of these two, or

$$\left(v + \frac{\delta\,v}{\delta\,x}\,dx\right)\,dt - v\,dt \;=\; \text{Formulas (10)} + (11),$$

or, inserting the values of Formulas (10) and (11) and simplifying,

$$\frac{\delta\,v}{\delta\,x} = \left(\frac{1}{K} + \frac{D}{E\,b}\right)\,W\,\frac{\delta\,y}{\delta\,t},$$

which is the second equation necessary.

Let

$$\frac{1}{a^2} = \frac{W}{g}\left(\frac{1}{K} + \frac{D}{E\,b}\right);^*$$

$$a = \sqrt{\frac{g}{W\left(\frac{1}{K} + \frac{D}{E\,b}\right)}} \qquad \ldots\ldots(12)$$

substituting this,

$$\frac{\delta\,v}{\delta\,x} = \frac{g}{a^2}\,\frac{\delta\,y}{\delta\,t} \qquad \ldots\ldots(13)$$

*a is really the velocity of the wave along the pipe, as is seen from Formulas (9A) or (14).

By elimination of v in Equations (9) and (13) we get the common wave equation,

$$\frac{\delta^2 y}{\delta x^2} = \frac{1}{a^2}\frac{\delta^2 y}{\delta t^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9A)$$

likewise,

$$\frac{\delta^2 v}{\delta x^2} = \frac{1}{a^2}\frac{\delta^2 v}{\delta t^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13A)$$

A general solution of Equations (9) and (13), or (9A) and (13A), is

$$y = Y + F\left(t - \frac{x}{a}\right) - f\left(t + \frac{x}{a}\right)^* \quad \ldots\ldots\ldots (14)$$

$$v = V - \frac{g}{a}\left[F\left(t - \frac{x}{a}\right) + f\left(t + \frac{x}{a}\right)\right]$$

these being general expressions for waves traveling in both directions with velocity, a.

Introducing in the first part of Equation (14) the fact that when $x = L$, $y = Y$, for all values of t, we get

$$f\left(t + \frac{L}{a}\right) = F\left(t - \frac{L}{a}\right) \quad \ldots\ldots\ldots\ldots\ldots (15)$$

To get rid of the unknown function, $f\left(t + \frac{x}{a}\right)$, we may express it in terms of F. To do this, choose t_1 so that

$$\left.\begin{aligned} t_1 + \frac{L}{a} &= t + \frac{x}{a} \\ t_1 - \frac{L}{a} &= t + \frac{x}{a} - \frac{2L}{a} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots (16)$$

Therefore, from Equations (15) and (16),

$$f\left(t + \frac{x}{a}\right) = f\left(t_1 + \frac{L}{a}\right) = F\left(t_1 - \frac{L}{a}\right) = F\left(t + \frac{x}{a} - \frac{2L}{a}\right). \quad (17)$$

Formulas (17) and (14) give

$$\left.\begin{aligned} y &= Y + F\left(t - \frac{x}{a}\right) - F\left(t + \frac{x}{a} - \frac{2L}{a}\right) \\ v &= V - \frac{g}{a}\left[F\left(t - \frac{x}{a}\right) + F\left(t + \frac{x}{a} - \frac{2L}{a}\right)\right] \end{aligned}\right\} \quad \ldots\ldots (18)$$

By Taylor's theorem

$$\left.\begin{aligned} F\left(t - \frac{x}{a}\right) &= F(t) - \frac{x}{a}F'(t) + \Sigma_1 \\ F\left(t + \frac{x}{a} - \frac{2L}{a}\right) &= F(t) - \frac{2L - x}{a}F'(t) + \Sigma_2 \end{aligned}\right\} \quad \ldots\ldots (19)$$

*For inclined pipes this would have a term, $-x \sin. \alpha$, which would disappear at $x = 0$, the gate.

in which Σ_1 and Σ_2 represent terms containing derivatives of $F(t)$ of higher order. If we now suppose Σ_1 and Σ_2 to be negligible,* substituting Equation (19) in Equation (18), we get

$$y = Y + 2\frac{L-x}{a}F'(t). \quad \ldots\ldots\ldots\ldots\ldots\ldots (20)$$

$$v = V - \frac{2g}{a}\left[F(t) - \frac{L}{a}F'(t)\right].$$

We assume the rise of pressure to be at a constant rate until the wave returns, that is

$$F'(t) = \text{constant}.$$

Thus, by Equation (20), as y_0 and v_0 are the values of y and v, respectively, at $x = 0$ (the gate),

$$\frac{dy_0}{dt} = 0 \text{ and } \frac{d^2 v_0}{dt^2} = 0$$

at any time after the reflected wave returns. As the equation of flow (neglecting friction) is

$$u^2 = \frac{v_0^2}{[\psi(t)]^2} = 2gy_0$$

and as $\frac{dy_0}{dt} = 0$ (the assumption of linearity),

$$\frac{dv_0}{dt} = \psi'(t)\sqrt{2gy_0}.$$

Differentiating the second part of Equation (20) for $x = 0$, $v = v_0$, we get

$$\frac{dv_0}{dt} = -\frac{2g}{a}F'(t).$$

Equating these two we get a value of $F'(t)$ which, substituted in the first part of Equation (20), gives a second degree equation in y_0 from which h, or $y_0 - Y$, can be obtained. Now, remembering that from linearity, $\psi'(t) = -\frac{V}{T\sqrt{2gY}}$,† and calling $N = \left(\frac{LV}{gTY}\right)^2$

$$\frac{y_0^2}{Y^2} - 2\frac{y_0}{Y}\left[1 + \frac{1}{2}\left(\frac{LV}{gTY}\right)^2\right] + 1 = 0. \quad \ldots\ldots\ldots (21)$$

* Σ_1 is not negligible if $\frac{x}{a} > t$, as the wave has not yet arrived at the point. Likewise, Σ_2 is not negligible if $\frac{2L-x}{a} > t$, as the reflected wave has not yet got back there. Therefore, the following formulas are incorrect if the time of closing is less than $\frac{2L}{a}$. Mathematically, this follows, because F is defined by different algebraic expressions for positive and negative values of its argument. Thus, a Taylor's series for positive values will not hold for negative values.

† This brings in the assumption of linear gate closing, which is used here only. This is probably inconsistent with the other assumption of linear rise of pressure.

Solving this, and putting $h = y_0 - Y$, since $t > \frac{2L}{a}$,

$$\left.\begin{aligned} \frac{h}{Y} &= \frac{N}{2} \pm \sqrt{\frac{N^2}{4} + N} \\ h &= \frac{NY}{2} \pm Y\sqrt{\frac{N^2}{4} + N} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots (C)$$

As a matter of fact, this formula becomes inaccurate as it approaches $\frac{2L}{a}$. This discrepancy must be due to some error in the assumptions. The assumption that ψ (t) and F (t) are both linear functions seems to be most open to question.

Experiments have shown that F (t) (the rise of pressure) is often linear. Therefore, the other assumption, namely, that ψ (t) (rate of closing of gate), is at the same time linear is probably at fault. This latter assumption is not used in obtaining Formula (B).

The minus sign in Formula (C) is supposed to apply in opening the gates, and the drop of pressure, according to the formula, can never exceed Y, but approaches it as a limit.

Surge in Surge Tanks.

The problem of ordinary surge-tank design is simple, as far as the theory and fundamental assumptions are concerned. In starting up, the water is at rest in the entire system. Suddenly the load is thrown on, and, assuming that the full load flow is immediately drawn from the surge tank, a known quantity of water is drawn out, and the quantity of water coming in depends on the difference in head between the surge tank and the reservoir.

Neglecting friction, this problem is of the simplest, and can be derived at once from work and energy. The answer is the same, either for starting or stopping the plant.

When friction is considered, the fundamental equations are still simple to set up, but the solution becomes difficult, even with the aid of the higher mathematics. The following solution is offered by Dr. D. L. Webster, of the Physics Department of Harvard University:

To determine the motion of the water in the pipe, consider the work done on it and the kinetic energy it acquires in moving an

infinitesimal distance, dx. The amounts of work done by various forces are as follows:

(*a*) By gravity: $(W\,P\,dx)\,s$

(*b*) By friction: $(W\,P\,dx)\,\left(-f\,\frac{v^2}{V^2}\right)$,

f being the head loss by friction alone at the limiting velocity, V, and, therefore, $f\,\frac{v^2}{V^2}$ being the loss at the velocity, v. (Friction varies as velocity squared.)

The kinetic energy acquired by the water in the pipe at the same time is $\frac{W\,P\,L}{g}\,d\left(\frac{v^2}{2}\right) = \frac{W\,P\,L}{g}\,v\,dv$; and the energy acquired by the water entering the pipe is $W\,\frac{P\,dx}{g}\,\frac{v^2}{2}$.

Equating the work done to the energy acquired, we find

$$\left[s - f\,\frac{v^2}{V^2} - \frac{v^2}{2\,g}\right]dx = \frac{L}{g}\,v\,dv \quad \ldots\ldots\ldots\ldots\ldots (21)$$

or, as $dx = v\,dt$,

$$\frac{d\,v}{dt} = \frac{g}{L}\left[s - \left(\frac{f}{V^2} + \frac{1}{2\,g}\right)v^2\right] \quad \ldots\ldots\ldots\ldots\ldots (22)$$

This equation may be further simplified by noticing that, in a steady condition, s becomes the final head loss, F, by friction and entrance to the pipe together, and $\frac{d\,v}{dt}$ becomes zero and $v = V$, whence

$$F = f + \frac{V^2}{2\,g} \quad \ldots\ldots\ldots\ldots\ldots (23)$$

and

$$\frac{d\,v}{dt} = \frac{g}{L}\left[s - F\,\frac{v^2}{V^2}\right] \quad \ldots\ldots\ldots\ldots\ldots (24)$$

In this equation, v and s are both variables, dependent on t, so that, as s is the one in which we are interested, it would be well to express the equation in terms of t, s, $\frac{d\,s}{dt}$, and $\frac{d^2\,s}{dt^2}$. This we may do by using the equation

$$A\,s = Q\,t - P\,x \quad \ldots\ldots\ldots\ldots\ldots (25)$$

derived by considering the volumes leaving and entering the standpipe. By differentiating Equation (25), we may obtain

$$A\,\frac{d\,s}{dt} = Q - P\,v, \quad A\,\frac{d^2\,s}{dt^2} = -\,P\,\frac{d\,v}{dt} \quad \ldots\ldots\ldots (26)$$

Therefore, substituting in Equation (24),

$$\frac{d^2 s}{dt^2} - \frac{g F}{P L A V^2}\left(Q - A\frac{d s}{dt}\right)^2 + \frac{g P}{L A} s = 0 \ldots\ldots (27)$$

As it is impossible to integrate this equation, we must make some approximation, preferably one that will make the maximum drawdown greater, rather than less, than its real value, and thus be on the safe side. Such an approximation may be obtained by considering the head loss by friction and entrance proportional to the velocity, rather than to its square, having the actual value, F, when $v = V$, and therefore, a greater value for all smaller velocities.

Thus we may replace $F\frac{v^2}{V^2}$ in Equation (24) by $F\frac{v}{V}$ and replace Equation (27) by

$$\frac{d^2 s}{dt^2} + \frac{g F}{L V}\frac{d s}{dt} + \frac{g P s}{L A} = \frac{g F Q}{L A V} = \frac{g P F}{L A} \ldots\ldots (28)$$

When a steady condition is reached, with $v = V$, $\frac{d s}{dt}$ and $\frac{d^2 s}{dt^2}$ will be zero, and we shall have s equal to F, as we have seen above, or as we can derive from Equation (28), remembering that $\frac{Q}{P} = V$. Letting $s' = s - F$, $2k = \frac{g F}{L V}$, and $n^2 = \frac{g P}{L A}$, Equation (28) becomes

$$\frac{d^2 s'}{dt^2} + 2k\frac{d s'}{dt} + n^2 s' = 0 \ldots\ldots (29)$$

This equation is the common form for damped harmonic vibrations, and is treated at length in many text books on the calculus, such as Osgood's, where the general solution is shown to be of the form

$$s' = C_1 e^{-kt} \cos.\ n' t + C_2 e^{-kt} \sin.\ n' t \ldots\ldots (30)$$

where $n' = \sqrt{n^2 - k^2}$, and C_1 and C_2 are arbitrary constants to be determined from the initial conditions of the problem.

For the case where full power is turned on, with the water in the conduit initially at rest, we have when

$$t = 0, s' = -F \text{ and } \frac{d s'}{dt} = \frac{Q}{A} \ldots\ldots (31)$$

From these we may at once obtain

$$C_1 = -F, \text{ and } -C_1 k + C_2 n' = \frac{Q}{A} \ldots\ldots (32)$$

or

$$s = F\left[1 - e^{-kt}\left(\cos.\ n' t + \frac{k}{n'} \sin.\ n' t\right)\right] + \frac{Q}{A n'} e^{-kt} \sin.\ n' t \ldots\ldots (33)$$

To find the maximum draw-down, we have now merely to differentiate this and set the derivative equal to zero.

Thus we find

$$\frac{ds}{dt} = e^{-kt}\left[F\left\{ k\left(\cos.\ n'\,t + \frac{k}{n'}\sin.\ n'\,t\right) + n'\sin.\ n'\,t - k\cos.\ n'\,t\right\} + \frac{Q}{A}\left(\cos.\ n'\,t - \frac{k}{n'}\sin.\ n'\,t\right)\right]$$

$$= e^{-kt}\left[F\frac{n^2}{n'}\sin.\ n'\,t + \frac{Q}{A}\left(\cos.\ n'\,t - \frac{k}{n'}\sin.\ n'\,t\right)\right] = 0. \quad (34)$$

This expression equals zero when

$$\tan.\ n'\,t = -\frac{n'}{\frac{FA}{Q}n^2 - k} = \frac{-n'}{k},\quad \cos.\ n'\,t = -\frac{k}{n},$$

$$\sin.\ n'\,t = +\frac{n'}{n}$$

Let t_1 = this value of t, when s is at its maximum, S.

From Equation (33) at time, t_1, $s = S$, where

$$S = F\left\{1 - e^{-kt_1}\left(-\frac{k}{n} + \frac{k}{n}\right)\right\} + \frac{Q}{An'}e^{-kt_1}\frac{n'}{n},$$

or,
$$S = F + \frac{Q}{An}e^{-kt_1} = F + Q\sqrt{\frac{L}{gAP}}e^{-kt_1}. \quad (35)$$

This can be put in simpler form, for

$$kt_1 = \frac{k}{n'}\left(\pi - \cos.^{-1}\frac{k}{n}\right) \quad (36)$$

and

$$\frac{k}{n} = \frac{F}{2Q}\sqrt{\frac{AgP}{L}} = m, \text{ and } \frac{k}{n'} = \frac{m}{\sqrt{1-m^2}} = m'$$

Therefore, $k\,t_1 = m'\,(\pi - \cos.^{-1} m)$, and Equation (35) becomes

$$S = F + \frac{Q\sqrt{\frac{L}{gAP}}}{e^{m'(\pi - \cos.^{-1} m)}} = F\left[1 + \frac{1}{2me^{m'(\pi - \cos.^{-1} m)}}\right]. \quad (G)$$

This is the best approximation obtainable by this method.

The time required for a full cycle is $\tau = \frac{2\pi}{n'}$ (36A)

where $n' = \sqrt{n^2 - k^2} = n\sqrt{1-m^2} = \sqrt{\frac{gP}{LA}}\sqrt{1-m^2}$.

Thus $\tau = 2\pi\sqrt{\frac{L\,A}{g\,P} + \frac{F^2\,A^2}{4\,V^2\,P^2}}$, approximately.

The time from starting to maximum draw-down is, from Equation (36)

$$t_1 = \frac{1}{n'}(\pi - \cos.^{-1} m) > \frac{\tau}{4}$$

A second best approximation for S may be obtained, as $\frac{k}{n}$ is small, by taking $n' = n$ and

$$\cos.^{-1}\frac{k}{n} = \frac{\pi}{2} \text{ and } k\,t_1 = \frac{\pi\,k}{2\,n} \ldots\ldots\ldots\ldots\ldots\ldots (37)$$

This gives, for this rougher approximation,

$$S = F + V\sqrt{\frac{L\,P}{g\,A}}\,e^{-\frac{\pi\,m}{2}} = F + \frac{Q\sqrt{\frac{L}{A\,g\,P}}}{e^{\frac{\pi\,m}{2}}} = F\left[1 + \frac{1}{2\,m\,e^{\frac{\pi\,m}{2}}}\right] \ldots\ldots (F)$$

A very rough approximation obtained from Equation (G), neglecting the effect of friction in damping the vibrations, though not in determining the final position, is

$$S = F + Q\sqrt{\frac{L}{g\,A\,P}} = F\left[1 + \frac{1}{2\,m}\right] \ldots\ldots\ldots\ldots (E)$$

A point to be noticed about these approximations is that the best, expressed by Equation (G), should give an answer slightly above the true one, the next best, Equation (F), somewhat higher, and the third best, Equation (E), the highest of all.

Although the most important quantity in the design of a surge tank is the maximum draw-down when throwing on the full load, with the water in the conduit initially at rest, the rise when the full power is suddenly shut off is also important, and may be found as a by-product of the foregoing analysis.

For this problem, the principal change in the analysis is the dropping of the term, Qt, in Equation (25), and the terms, such as the right hand side of Equation (28), that result from it. At the same time, the initial conditions must be changed to

$$s = +F \text{ and } \frac{ds}{dt} = -\frac{Q}{A} \ldots\ldots\ldots\ldots\ldots (31A)$$

at $t = 0$; so that s is determined exactly as s' was in the previous work, but with the sign reversed. The new algebraic minimum value

of s, therefore, will be equal to minus the above maximum of s', making the maximum rise above the position of static equilibrium,

$$Q\sqrt{\frac{L}{g\,A\,P}}\,e^{-k\,t_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (38)$$

exactly as in Equation (35).

Thus it appears that the rise of the water from its position of kinetic equilibrium is exactly like its previous drop from its position of static equilibrium, so that the maximum height above the static position is less than the maximum draw-down from it by the distance, F, between the equilibrium positions.

Neglecting friction entirely, we get from Equation (E)

$$S = V\sqrt{\frac{L\,P}{g\,A}} = Q\sqrt{\frac{L}{g\,A\,P}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (D)$$

which is true for either starting or stopping.

This simple form can be checked at once by work and energy, since the work done in the surge tank is $\frac{1}{2}\,S^2\,W\,A$, and the work done in starting or stopping the water equals its kinetic energy, or $\frac{W\,P\,L\,V^2}{2\,g}$; equating these

$$\frac{1}{2}\,W\,A\,S^2 = \frac{1}{2}\,W\,\frac{P\,L\,V^2}{g}$$

$$S = V\sqrt{\frac{L\,P}{g\,A}} = Q\sqrt{\frac{L}{g\,A\,P}} \text{ as before} \quad \ldots\ldots\ldots\ldots (D)$$

Economical Size of Penstock.

In developments involving the use of long flow lines, or pipes under a high head, the cost of the pipe line is sometimes the largest part of the total cost. For this reason its most economical size becomes a matter of the greatest importance.

The following formula was first derived for a rough check on the independent calculations of several engineers in determining the best size for a certain pipe. The result of the somewhat academic mathematical treatment was so simple that it led the writer to suspect its practical value. It was not until after it had been checked repeatedly by other methods, starting with quite different assumptions, that it seemed sufficiently useful to present for general use.

One point especially should be emphasized, namely, that a wide variation in the assumptions will lead to a comparatively slight variation in result, and the first approximation in which the assumptions may be fairly rough will generally yield a result very close to the final figure. For instance, a variation of 100% in any one of the assumptions will make a difference of 1 ft., only, in a 10-ft. pipe.

Derivation.—By the Chezy formula, the head lost in a pipe is

$$\frac{L\,V^2}{C^2\,R}\text{ feet}\qquad(40)$$

where $$R = \frac{D}{4}.$$

The income lost from this loss of head is

$$\frac{L\,V^2}{C^2\,R}\,i\text{ dollars per year}\qquad(41)$$

This is clear loss, as the operating and maintenance expenses of the plant are assumed to be fixed.

The other factor which must be considered is the annual fixed charge on the pipe. This is

$$\frac{p}{100}\,B\,L\,D\text{ dollars per year}\qquad(42)$$

It is clear that the sum of these two factors is the total yearly loss, and a pipe having a diameter which will make this sum a minimum will be most economical. Adding these and inserting the value $R = \frac{D}{4}$ and $V = \frac{q}{\frac{\pi D^2}{4}}$, the yearly loss is

$$\frac{16 \times 4 \times L\,q^2\,i}{C^2\,D^4\,\pi^2\,D} + \frac{p\,B\,L\,D}{100}\qquad(43)$$

or simplifying,

$$\frac{6.5\,L\,q^2\,i}{C^2\,D^5} + \frac{p\,B\,L\,D}{100}\qquad(44)$$

In order to get the minimum value of this expression, with variation of D, it is merely necessary to differentiate once and set equal to zero.

$$0 = \frac{-5 \times 6.5 \times L\,q^2\,i}{C^2\,D^6} + \frac{p\,B\,L}{100}\qquad(45)$$

$$\frac{3\,250\,L\,q^2\,i}{C^2\,D^6} = p\,B\,L\qquad(46)$$

$$D = \sqrt[6]{\frac{3\,250\,q^2\,i}{C^2\,p\,B}}\qquad(H)$$

Assumptions.—The foregoing formula depends for its accuracy on the exactness of the factors which enter into it, and although these may be varied considerably without materially affecting the results, nevertheless certain principles should be carefully noted.

Flow Through Penstock.—The most difficult factor to select in Equation (*H*) is q, the flow through the penstock.

In a plant with a single pipe line running at full load all its operating time, and under a constant head, the full load flow, Q, would of course be used. In other plants the probable operating conditions must be known and q selected accordingly. Certain generalities, however, apply to all cases.

Where there is more than one penstock, it is assumed that each one will carry a proportional part of the load throughout the year, even though one of them may seldom be used.

If a typical daily load curve can be assumed the flow at each hour of the day can be obtained and the square root of the average square may be used for q. The average is not used, for the loss of head varies as the velocity squared, and not as the velocity. The only time considered should be that in which the plant is in active operation, for when it is closed down, or when the wheels are merely turning over, there is no income being earned and the loss of head, if any, makes no difference.

As a matter of interest, it may be said that in several cases which were studied, with load factors varying from 10 to 40%, the value of q chosen was about 80% of the full load flow.

Income per Foot of Head.—The income per foot of head is the total gross income of the plant divided by the average net head and the number of penstocks. It was calculated that a 10 000-kw. plant with four penstocks under a 100-ft. head would earn $160 000 gross per year, or $40 000 per unit. This gives $400 per year per foot of head for each penstock, but for six-tenths of the year there was an excess of water and a loss of 2 or 3 ft. in the penstock could be offset by opening the gate and using more water at a sacrifice of efficiency. Therefore, only $160 a year should be used for i in this case, as it is only during low-water periods that a larger penstock will earn additional income.

Percentage of Investment.—The percentage return on the investment which the initial cost of the penstocks is expected to give covers

fixed charges, depreciation, taxes, profit, and in fact everything. The profit should be the same as that which the total plant investment is expected to yield.

Cost of Penstock.—The formula assumes that the cost of the penstock in place varies as the diameter. This assumption is very close to the truth, within the narrow limits in which the penstock size may vary. For this variation the commercial thickness of plates or staves is the determining factor in pipe cost. The quantities of excavation and back-fill vary with the diameter squared, but it would not be proper to assume that the cost varied correspondingly, as the equipment, fixed charges, etc., form so large a part that a small percentage change in quantities would vary the cost more nearly as the diameter than as the square of the diameter.

For the first trial a penstock size must be assumed before the cost can be estimated or the formula used. If the economical size differs greatly from this, a new value of B may have to be tried.

Summary of Formulas Proposed by Other Writers.

Maximum Water-Hammer.—All formulas for instantaneous closing agree, however they may be deduced. At first sight they may seem to differ, but by simplifying they all reduce to the same form. In several standard books, however, typographical errors and a confusion between feet and inches lead to erroneous results.

Ordinary Water-Hammer.—Several other formulas have been proposed—deduced from work and energy, or impulse and momentum, or from assumption and experiment.

The following formula is given by D. W. Mead, M. Am. Soc. C. E.,* as a general expression for water-hammer. It is also given by Mr. Uhl in his paper,† but he considers it less accurate than Allievi's formula.

Assuming a head, h, caused by the closing of the gate and acting throughout the time, T, by impulse and momentum

$$P\,Wh\,T = \frac{W\,L\,P\,V}{g}$$

$$h = \frac{L\,V}{g\,T} \qquad (47)$$

* "Water Power Engineering," p. 450.

† *Transactions*, Am. Soc. Mech. Engrs., Vol. 34, p. 347.

This is erroneous, as it neglects the time, $\frac{2\,L}{a}$, required for the pressure wave to travel up the pipe before h becomes constant. This error is most important in small values of T, and for such values may yield results 50% too small.

This error is negligible, however, for larger values, and for such the formula is sufficiently accurate. It also neglects water entering and leaving the pipe, and thereby introduces a slight error for very large values of T.

This formula may be obtained at once as a special case of the general formula

$$h = \frac{L\,V}{g\left(T - \frac{L}{a}\right)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (B)$$

by neglecting $\frac{L}{a}$ when T is comparatively large. It is evidently 50% in error, however, when $T = \frac{2\,L}{a}$.

I. P. Church, Assoc. Am. Soc. C. E., quotes the following formula of Joukovsky,* and Mansfield Merriman,† M. Am. Soc. C. E., also gives it, but states that it is not applicable to all cases.

It is derived as follows: We have shown (Formula (7)) that the maximum water-hammer is $h = \frac{V\,a}{g}$. In this case the gate is closed instantaneously, or before any reflected waves have arrived to cut down the pressure. These arrive in the time, $\frac{2\,L}{a}$, so it has been erroneously assumed that, if the gate is closed in a longer time, the rise of pressure is proportionally less. Writing the proportion

$$h : \frac{V\,a}{g} :: \frac{2\,L}{a} : T,$$

$$h = \frac{V\,a}{g}\,\frac{2\,L}{a\,T} = \frac{2\,L\,V}{g\,T} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (48)$$

This formula is wrong, theoretically, and does not agree with practice or experiment, except for the special case where $T = \frac{2\,L}{a}$, when it becomes the common formula, $h = \frac{V\,a}{g}$. It can be used for small values only, and for larger values may be almost 100% in error.

* "Hydraulic Motors," p. 209.
† "Hydraulics," p. 391.

Surge in Surge Tanks.—Mr. R. D. Johnson has derived the following equation for maximum surge in surge tanks:

$$S = \sqrt{\frac{P\,L\,V^2}{A\,g} + F^2}$$

$$t_1 = \frac{\pi}{2}\sqrt{\frac{L\,A}{g\,P} + \frac{C^2\,V^2\,A^2}{P^2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (49)$$

where $F = C\,V^2$.

The writer has derived, for an approximation:

$$S = \sqrt{\frac{P\,L\,V^2}{A\,g} + \frac{F^2}{9} + \frac{1}{3}F} \quad \ldots\ldots\ldots\ldots\ldots\ldots (50)$$

Mr. D. W. Mead has the following formulas:

Neglecting friction, but including governor action, S, for a drop in level is given by

$$S^2 - 2\,Y\,S = -\frac{2\,P}{A}\left(\frac{L\,V^2}{2\,g} + \frac{Y\,T\,V}{\pi}\right) \quad \ldots\ldots\ldots\ldots (51)$$

where $$T = \pi\sqrt{\frac{A\,L}{P\,g}}.$$

To this F must be added to approximate friction. . . . . (52)

Including friction, Mr. Mead gives for upward surge:

$$S = \sqrt{\frac{P\,L\,V^2}{A\,g} - \frac{F\,T\,Q}{3\,A}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (53)$$

His most exact formula is

$$S^2 - 2\,(Y - F)\,S = -\frac{2\,P}{A}\left(\frac{L\,V^2}{2\,g} - C\,V^3\,(0.37\,T_1) + \frac{Y\,T_1\,V}{\pi}\right) \ldots (54)$$

Where $$C = \frac{F}{V^2}$$

$$\frac{\tau}{2} = T = \pi\sqrt{\frac{L\,A}{P\,g}} \text{ (no friction or governor)}$$

$$G = \sqrt{\frac{P\,L\,V^2}{A\,g}} \text{ (as above)}$$

J = answer to Mead's Equation (51) (no friction)

$$T_1 = \frac{J}{G}\,T.$$

Economical Size of Penstocks.—Using the same methods, a similar formula for economical penstock size can be developed, assuming that the pipe thickness varies as the diameter squared. This is sometimes theoretically true, but practically long lengths of the pipe are

made of constant thickness, and the allowance of metal for rust and water-hammer is independent of the head. Therefore, the foregoing formula is preferable, as it is more simple.

Numerical Examples.

Maximum Water-Hammer.

Formula (*A*).—A penstock, 10 ft. in diameter, ½ in. thick, and 400 ft. long, has water flowing in it at 6 ft. per sec. The gate is under a 100-ft. head. The maximum rise of pressure that can develop due to closing the gate is (Formula (*A*)):

$$D = 10$$
$$b = 0.041$$
$$L = 400$$
$$Y = 100$$
$$V = 6$$

$$\frac{D}{b} = \frac{10 \times 12}{\frac{1}{2}} = 240$$

$$h = \frac{145\ V}{\sqrt{1 + 0.01\ \frac{D}{b}}} = \frac{145 \times 6}{\sqrt{1 + 0.01 \times 240}}$$

$$= \frac{870}{\sqrt{3.4}} = 465 \text{ ft.}$$

To this must be added the static head (100 ft.) making a total pressure at the gate of 565 ft., or 245 lb. per sq. in.

Ordinary Water-Hammer.

In order to test out and show the limitations of the four formulas for ordinary water-hammer, three cases are worked out:

Case I.—The foregoing data are used, with a closing time of 5 sec.

Case II.—The foregoing data are used, with a closing time of 0.32 sec.

Case III.—The foregoing data are used, with a closing time of 0.32 sec., but the head, *Y*, is taken as 400 ft., and not 100 ft.

Case I.

Using the foregoing data, with a closing time of 5 sec.

Formula (*B*).—By Formula (*B*),

$$h = \frac{L\,V}{g\left(T - \frac{L}{a}\right)},$$

where, for steel pipe, $a = \dfrac{4\,660}{\sqrt{1 + 0.01\frac{D}{b}}}$,

$$a = \frac{4\,660}{\sqrt{3.4}} = 2\,500, \frac{L}{a} = \frac{400}{2\,500} = 0.16,$$

$$h = \frac{400 \times 6}{32.2\ (5 - 0.16)} = 15.5 \text{ ft.}$$

Therefore, the total maximum head is 115.5 ft.

Formula (*C*).—From Formula (*C*),

$$h = \frac{N\,Y}{2} + Y\sqrt{\frac{N^2}{4} + N}$$

$$N = \left(\frac{L\,V}{g\,T\,Y}\right)^2 = \left(\frac{400 \times 6}{32.2 \times 5 \times 100}\right)^2 = 0.0222,$$

$$h = \frac{0.0222 \times 100}{2} + 100\sqrt{\frac{0.0222^2}{4} + 0.0222} = 16.1 \text{ ft.}$$

Formula (*47*).—Formula (47) gives

$$h = \frac{L\,V}{g\,T} = \frac{400 \times 6}{32.2 \times 5} = 15 \text{ ft.}$$

Formula (*48*).—Formula (48) gives twice this, or

$$h = \frac{2\,L\,V}{g\,T} = 30 \text{ ft.}$$

Case II.

Taking the same data, with a closing time of exactly $\dfrac{2\,L}{a} = 0.32$ sec., we know we should get the same results as from Formula (*A*), maximum water-hammer (465 ft.). Using the different formulas, we get the following:

Formula (*B*) $h = \dfrac{400 \times 6}{32.2\ (0.32 - 0.16)} = 465$

" (*C*) $N = 5.4, h = \dfrac{540}{2} + 100\sqrt{\dfrac{5.4^2}{4}} + 5.4 = 630$

" (47) $h = \dfrac{2\,400}{32.2 \times 0.32} = 232$

" (48) $h = \dfrac{4\,800}{32.2 \times 0.32} = 465$

Case III.

Taking Case II, with a head of 400 ft., the only formula which will be altered is Formula (*C*).

With $Y = 400$, $N = 0.34$, $h = \frac{0.34 \times 400}{2} + 400\sqrt{\frac{0.34^2}{4} + 0.34} = 312.$

Table 1 is a comparison of the foregoing.

TABLE 1.—COMPARISON OF RESULTS.

Case.	Value of *T*.	Value of *Y*.	Formula.	Head. in feet.	Percentage of difference.
I	5 sec.....	100 ft.	(*B*) Correct formula.....	15.5	0
			(*C*) Allievi.....	16	+ 3%
			(47).....	15	− 3%
			(48).....	30	+ 94%
II	0.32 sec $= \frac{2L}{a}$...	100 ft.	(*A*) or (*B*) Correct formula.....	465	0
			(*C*) Allievi.....	630	+ 35%
			(47).....	232	− 50%
			(48).....	465	0
III	0.32 sec.....	400 ft	(*A*) or (*B*) Correct formula.....	465	0
			(*C*) Allievi.....	312	− 34%
			(47).....	232	− 50%
			(48).....	465	0

The comparison of numerical results in Table 1 for three different cases brings out the limitations of the various formulas very clearly, and establishes the following general rules:

Formula (*B*) is the best for general use.

Allievi (Formula (*C*)) is only good for comparatively slow closing times. For quick closing his formula is incorrect, and may give results too high or too low.

Formula (47) is useless for general application, but is a good check for slow closing of gates.

Formula (48) is useless for general application, but is a good check for quick closing of gates.

Surge in Surge Tanks.

Taking the following case: A pipe, 5 ft. in diameter, and 13 000 ft. long, is passing 112 cu. ft. of water per sec. at full load. There is a total loss of 20 ft. in the pipe running full. A surge tank 14 ft. in diameter is to be installed. The draw-down of the reservoir is 30 ft.

The average head on the wheels is 440 ft. Determine the minimum height of the surge tank required.

$Q = 112$;

$P =$ pipe area $= 19.6$ sq. ft.;

$L = 13\,000$ ft.;

$A =$ surge tank area $= 154$ sq. ft.;

$F = 20$ ft.;

$V =$ full load velocity $= \frac{112}{19.6} = 5.7$ ft. per sec.;

$Y = 440$ ft.

Insert these numerical values in the various formulas, and, solving for S, we get the results shown in Tables 2 and 3.

TABLE 2.—SURGE IN SURGE TANKS. RESULTS BY SEVERAL FORMULAS.

Conditions.	Formula.	Maximum surge in feet, S.	Percentage of difference.
Neglecting friction	(*D*) Common formula	41	0
	(51) D. W. Mead (First approximation including governor action)	45	+7%
Including friction	(*G*) D. L. Webster	46	0
	(49) R. D. Johnson	46	0
	(50) Writer's approximate formula	48	+6%
	(*F*) D. L. Webster (First approximate)	48	+6%
	(54) D. W. Mead (Most exact, friction and governor action)	50	10%
	(*E*) D. L. Webster (Second approximate)	61	35%
	(52) D. W. Mead (First approximate)	65	43%
Rise above reservoir level	(*G*) D. L. Webster	26	0
	(53) D. W. Mead	29	+12%

TABLE 3.—SURGE IN SURGE TANKS.

TIME FOR COMPLETE CYCLE; AND TIME TO MAXIMUM DRAW-DOWN (STARTING UP).

	Formula.	Time.	Percentage of difference from Formula (36).
Time for complete cycle	(36*A*) D. L. Webster	$\tau = 365$	0
	(54) D. W. Mead (including friction)	$\tau = 390$	+7%
	(51) D. W. Mead (no friction)	$\tau = 354$	−3%
Time to maximum draw-down (starting up)	(36) D. L. Webster	$t_1 = 102$ sec.	.....
	(49) R. D. Johnson	$t_1 = 99$ sec.	.....

From the results in Tables 2 and 3, using Webster's or Johnson's formula, the tank must rise 26 ft. above maximum reservoir level, and must extend 46 ft. below minimum reservoir level. Therefore, if the surge tank is 14 ft. in diameter, it must be $46 + 30 + 26 = 102$ ft. high.

Economical Penstock Size.

A development is to be built on a small stream by creating a very large reservoir which will completely equalize the flow of the stream; the water is to be conducted to the surge tank and penstocks by a single wood stave pipe, 13 000 ft. long. The head is 440 ft.; the average flow through the pipe while the plant is in operation is 112 cu. ft. per sec., which develops about 3 000 kw. There are two 2 000-kw. units. The plant is to be used as a base load plant, and the load is to be very nearly constant, therefore q may be assumed as 112 cu. ft. per sec.

The plant develops about 26 000 000 kw-hr. of primary power yearly, which, sold at 1 cent, will give a gross income of \$260 000, or \$590 per ft. of fall.

A velocity of 6 ft. per sec. is first assumed, which would require a 5-ft. pipe. Such a wood pipe, in place and back-filled, is estimated at \$10 per ft., or \$2 per ft. of diameter.

Inserting these values in the formula:

$q = 112$

$i = 590$

$C = 113$ (assumed constant for Chezy formula)

$p = 15\%$ (assumed for profit, maintenance, depreciation, etc.)

$B = \$2$.

$$d = \sqrt[6]{\frac{3\,250\,q^2\,i}{C^2\,p\,B}} = \sqrt[6]{\frac{3\,250 \times 112^2 \times 590}{113^2 \times 15 \times 2}}$$

$$= \sqrt[6]{6\,250} = 4.29 \text{ ft.}$$

A 4 ft. 3½-in. pipe is most economical, or, to make a more common size and err on the side of better regulation, say, a 4½-ft. pipe.

The writer wishes to acknowledge gratefully the help of Dr. D. L. Webster and the criticisms of George F. Swain, Past-President, Am. Soc. C. E., and Mr. J. F. Vaughan, in preparing this paper. The following books were also consulted.

THE DIFFERENTIAL SURGE TANK.

Discussion.*

By Roy Taylor, Esq.

Mr. Taylor.

Roy Taylor, Esq. (by letter).—In comparison with the great advancement made during recent years in all branches of hydro-electric work, progress in the matter of regulating long pipe lines seems to have remained practically stationary. With the exception of improvements in some details, regulating works to-day are built the same as those of ten years ago. In many cases even the idea of regulating the long water columns has been abandoned, and the fluctuations of draft have been taken care of by nozzle deflectors and waste weirs. The only explanation of this lack of progress seems to be that until recently only the attractive developments were undertaken where long pipe lines were not required. Troubles with electrical apparatus in the past were so common, and interruption in service so frequent that occasional poor hydraulic regulation was of small importance in comparison. To-day conditions are rapidly changing, electrical devices are far more reliable, interruptions are becoming more infrequent, and the desirability of satisfactory regulation without waste of water will soon become a necessity.

The most common type of hydraulic regulator now in operation, and the one most productive of good results, is an open storage tank or reservoir at the lower end of the pipe line. In the future, as the market for power grows, more and more of the less desirable developments requiring long pipe lines will attract attention, and this form of regulation will have even greater claim to importance. A certain few, however, where the ground at the lower end of the pipe line is

*This discussion (of the paper by Raymond D. Johnson, Esq., published in this number of *Proceedings*, and to be presented at the meeting of December 2d, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Taylor.

too low to make an open tank practicable, will have to depend on the less satisfactory though perfectly feasible device of air tanks. The differential principle is adaptable advantageously to them as well and is treated mathematically in Mr. Johnson's paper of 1908.

The form of open storage now in general use is a simple tank or reservoir with an unrestricted flow between it and the conduit. Many of these have been provided with overflows which although they waste water, are necessary to carry away excess water following shut-downs. In some cases, as for example that of the surge chamber at San Francisquito, Power Station No. 1, on the Los Angeles Aqueduct, it has been deemed necessary to go to great expense to provide sufficient capacity to insure good regulation. Many others have been intended to regulate under certain load changes, yet when put in operation have proved unsatisfactory, due probably to the coincidence of change of load with the periodic surges in the tank. Some find it possible to go on operating under these unstable conditions with poor regulation, and a few have been forced through expensive accidents to remodel their whole regulating works.

That practically all these disadvantages of the simple tank can be overcome, and the difficulties now arising in operating with some of them can, in a large measure, be relieved by the use of the differential principle, there is not the slightest doubt.

For equal regulating ability under the same load changes, the differential surge tank can be made (1) much smaller in diameter than the simple tank; (2) it does not have to be carried to such height as the latter, often saving an expensive spillway and waste of water; and (3), most important of all, it is proof against synchronous load changes, which, however small, are likely to carry the water in the ordinary simple tank beyond bounds, or at least to cause serious surging. The probability that load will be thrown on and off many times synchronously with the natural period of the water wave in the tank, may be slight, yet, as a possibility, it is always present, especially as the loads may be of almost any size and do not have to come directly in step with the water wave to cause serious surging. An example of the comparative effect of the same synchronous load changes on the operation of a differential and simple tank of equivalent capacities has been computed by the method of arithmetic integration, and is shown graphically in Fig. 3. It may be interesting to know that this diagram is taken from an actual study made for a proposed development. The surge in the simple tank soon increases beyond bounds, but, in the differential tank, it increases slightly until the choking action is enough to prevent further increase in the surging; and, if the same load changes are continued periodically, the surging remains at constant amplitude.

Mr. Taylor.

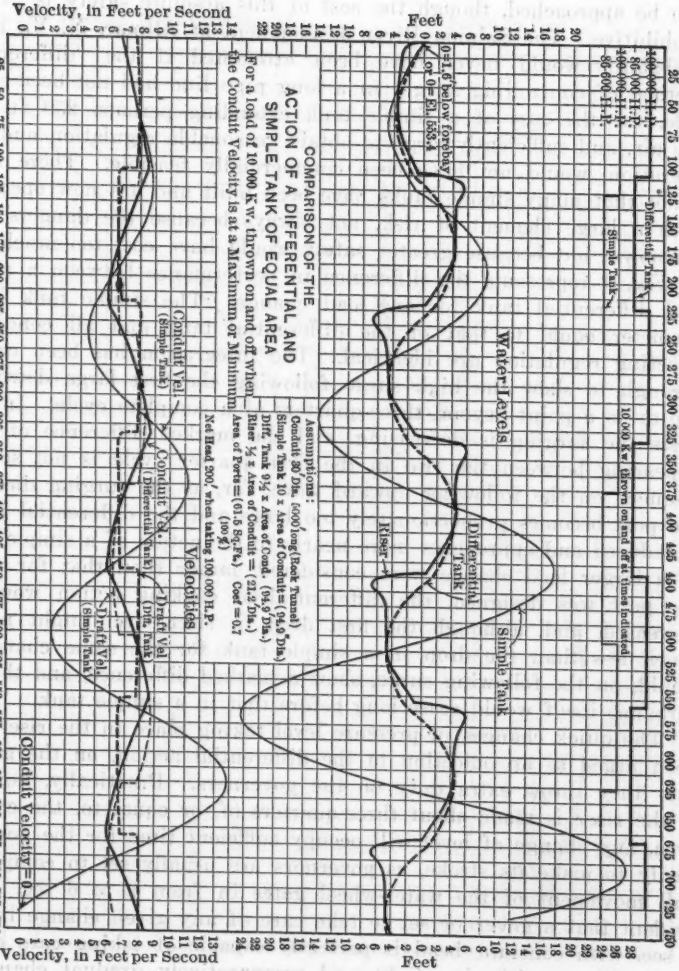

FIG. 3.

Mr. Taylor.

Although Fig. 3 represents very well the usual difference in performance to be found between the two types of tank, it must not be concluded that every simple tank will behave in this manner, for, by increasing the diameter sufficiently, a surging of constant amplitude can be approached, though the cost of this absolute safety is usually prohibitive. The Salmon River development at Altmar, N. Y., in all probability would never have been attempted if the "differential" method of controlling surges in a long pipe line had not been available, for the cost of a simple tank extending perhaps 250 ft. into the air, and sufficiently large to obtain reasonable regulation and safe operation, would not have been commercially feasible. There is no doubt that many simple tanks have been built and are now operating with a large element of risk, not always because the dangers were unknown, but because greater safety would have cost too much.

Fig. 4 represents the difference in performance between a simple and differential tank for one load change. The simple tank has a diameter equal to that of the differential tank and all conditions effecting regulation are identical. The integration has been carried through to show the high surge following the first large downward dip or to a point beyond three-quarters of a complete cycle. In both cases the surging is decreasing, and the marked difference of 5 ft. appearing between the two in the first quarter cycle is not so pronounced on the following upward wave, for, as the surging dies out, the port becomes proportionately too large and the differential action is reduced and approaches more nearly to the action of a simple tank. If a larger load change were considered, larger than that for which the port was designed, the differential or choking action would be increased, and, although the first drop in riser level might not be much less than the drop in a simple tank for the same change, it would, on the following surge, show a marked difference, and the disturbance itself would cease long before that in a simple tank.

The quick changes in pressure level taking place in the riser have been urged as an objection to the differential action, on the ground that they throw extra duty on the governors. Practically, however, if the riser is made about three-quarters of, or equal to, the conduit area, any change of level will occupy sufficient time for the governor easily to make its stroke, as governors are usually set to complete a full movement of the water-wheel gates in from 2 to 6 sec. It is evident that a governor set to take care of any given change in, say, 4 sec. with constant head is perfectly capable of taking care of the same change with the slight and comparatively gradual change in head which occurs in the riser in this short time.

Passing then to a detailed consideration of the differential principle, it is the primary object of this discussion to ascertain the degree of approximation attained in the use of the formulas derived by

Mr. Taylor.

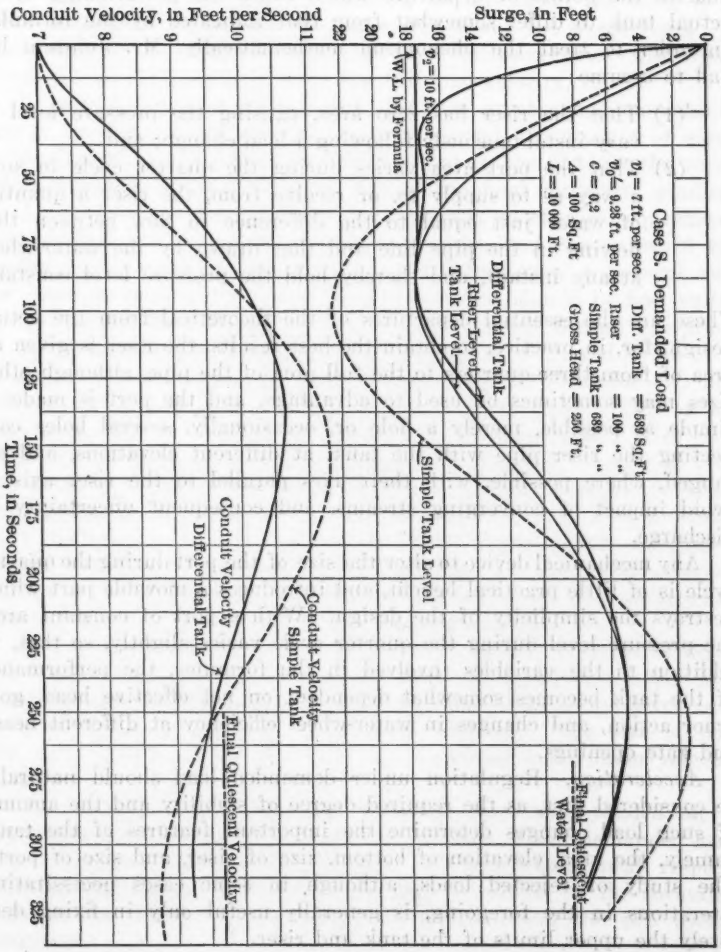

FIG. 4.

Mr. Taylor.

Mr. Johnson, and to demonstrate their value in arriving, in a comparatively short time, at the general design of a tank for any desired degree of regulation.

Before considering specific numerical cases, it may be well to emphasize the points of departure which cause the performance of an actual tank to differ somewhat from that indicated by the formulas. In order to treat the phenomena mathematically, Mr. Johnson has had to assume:

(1) That the riser has zero area, causing the pressure level to vary instantaneously following a load change; and

(2) That the port area varies during the quarter cycle in such a way as to supply to, or receive from, the riser a quantity of water just equal to the difference in flow between that flowing in the pipe line and that drawn by the water-wheel at any instant, and thereby hold the pressure level constant.

These are the essential departures of the theoretical from the actual design, for, in practice, to obtain the best results, the riser is given an area of from three-quarters to the full area of the pipe, although other sizes may sometimes be used to advantage, and the port is made as simple as possible, merely a hole or, occasionally, several holes connecting the riser pipe with the tank, at different elevations, and arranged, where possible, with their axes parallel to the riser axis to avoid impact of converging streams, and consequent uncertainty of discharge.

Any mechanical device to alter the size of the port during the quarter cycle is of little practical benefit, and introduces a movable part which destroys the simplicity of the design. With a port of constant area, the pressure level during the quarter cycle varies slightly, so that, in addition to the variables involved in the formulas, the performance of the tank becomes somewhat dependent on net effective head, governor action, and changes in water-wheel efficiency at different heads and gate openings.

Acceleration.—Regulation under demanded load should naturally be considered first, as the required degree of stability and the amount of such load changes determine the important features of the tank, namely, the area, elevation of bottom, size of riser, and size of ports. The study of rejected loads, although in some cases necessitating alterations in the foregoing, is generally useful only in fixing definitely the upper limits of the tank and riser.

Perhaps the best way to illustrate the use of Mr. Johnson's formulas is to consider a general method of procedure in arriving at a design. The length of pipe line, L, is the one factor most often determined at the start. The area, A, of the pipe line may be fixed, within comparatively narrow limits, by questions of economy. Assum-

Mr. Taylor.

ing that it is thus fixed, the value of c becomes a matter of judgment, depending on a knowledge of the frictional coefficient of the pipe material and the probable losses of head due to bends, etc. In fixing the elevation of the tank bottom, this should be given the highest value that could reasonably be expected, for the higher the value of c, other conditions remaining the same, the lower the surge level. A knowledge of the water-wheels and their characteristics will make it possible to estimate accurately the full load velocity, v_2.

It remains then to decide, first, for how great a sudden velocity change good regulation is desirable; and second, the amount of surge to be allowed, or the degree of stability, that is, the distance the water level should be allowed to drop beyond the final quiescent gradient level. The wide variation in load requirements, mechanical equipment, adaptability of the site for regulating works, and the value of the coefficient, c, make it impossible to formulate even a general rule for deciding these points. The design, however, should be best suited to the largest load change likely to occur during normal operation.

Adopting, then, a certain velocity change, $v_2 = v$, and value of k, y_1 and z can be computed. Substituting them in Equation (4) and solving for F will give the correct area for the tank. This is net tank area, and is exclusive of the area of the riser pipe. With very little further work, y_1 may be varied and its effect on the size of tank determined. Experiments with different velocity changes or other assumptions as to the probable value of c, can be tried, even a change in A, the area of the pipe line, may be found to give a more economical design. In short, by the use of the formulas, the whole field of possibilities can be investigated without needless work, and the combination adopted which is best suited to the exigencies of the case.

As for the elevation of the tank bottom, a liberal allowance of depth below the calculated surge should be made for occasional larger load demands and for absolute insurance against lower surge levels due to a coefficient of friction higher than expected. The size of port and upper limits of the tank will be considered later under rejected load.

To illustrate how closely the formulas may be depended on to approximate the actual performance of a design, under demanded load, four numerical cases have been selected, differing widely in all respects affecting regulation. They have been first calculated by the formulas, then by the method of arithmetic integration, and the two results compared.

The assumptions are given in Table 1.

In using the formulas, it is necessary to deal entirely with velocity changes, though, fundamentally, the load changes, in terms of power, are what influence the design. To change one into the other is comparatively simple, if it is remembered that v_2 is the conduit or draft

Mr. Taylor.

TABLE 1.

Case.	Length of pipe line, in feet. L.	Area of pipe, in square feet. A.	Gross head, in feet. H.	Frictional coefficient. c.	Velocity, in feet per second. v_1.	Velocity, in feet per second. v_2.	Stability, or k.
S	10 000	100	250	0.2	7	10	1.7
T	6 440	200	300	0.05	6	20	2.2
U	32 200	100	1 000	0.56	7.2	9	1.15
V	3 220	113	300	0.0555	12	24	1.05

velocity at the bottom of the surge, or end of the quarter cycle. The head at that time being less, the velocity change, $v_2 - v_1$, represents more than the actual load change by an amount depending on the size of surge and the net effective head. Expressing the relation mathematically:

$(H - c\,v_1^2)v_1$ = original power before load change,

$(H - c\,v_1^2)v_0^1$ = demanded power at instant load is thrown on and before riser level has dropped,

v_0^1 being the initial draft velocity for the new load, in terms of the conduit velocity.

$(H - c\,v_1^2 - y_1)v_2$ = demanded power at the end of the quarter cycle with riser level at the bottom of the surge.

As the demanded power must be held constant after the initial change,

$$(H - c\,v_1^2)v_0^1 = (H - c\,v_1^2 - y_1)v_2$$

Or the actual load change in horse-power can be expressed as follows:

$$\frac{A\,v_0^1\,(H - c\,v_1^2) \times 62.5 \times \text{Efficiency}}{550} - \frac{A\,v_1\,(H - c\,v_1^2) \times 62.5 \times \text{Efficiency}}{550}$$

and, if the water-wheel efficiency is assumed to be constant, as has been done throughout this discussion, the load change, in horse-power is

$$\frac{A\,(H - c\,v_1^2) \times \text{Efficiency}}{8.8}\,(v_0^1 - v_1).$$

The results obtained for the trial cases by Mr. Johnson's formulas, and using his nomenclature, are given in Table 2.

The same cases were then computed by using arithmetic integration, following the changes in velocity and water levels second by second. A head had to be assumed and the velocity change at the start corresponding to the load change calculated. As the head at the quarter

Mr. Taylor.

cycle was unknown without a trial, that given by the formulas in Table 2 was used, and the value of v_0^1 computed from $v_2 \times$ net head quarter cycle $= v_0^1 \times$ net head at start. The initial velocity change is then $v_0^1 - v_1$, and as the pressure level in the riser drops, v^1, the draft velocity, increases to a value, v_2, to hold the power constant. The resulting surge was found to be near enough to the assumed value to require no revision of the value v_0^1.

TABLE 2.

Case.	Z.	F, in square feet.	y_1, in feet.	t, in inches.	a_0, in square feet.	a_1, in square feet.

V	24.43	2 088	25.2	134	33.7	9.25

The friction and velocity head in the riser and the inertia of the water in both tank and riser were neglected, and 3 sec. were allowed for the governors to open up the turbine gates. A riser area equal to A was used, and the water-wheel efficiencies were assumed to remain constant. The work was first carried through using a port equal to a_0 and then, by trial and error, the best size of port was determined and the resulting performance calculated. The best size is one which gives an initial drop in the riser level equal to the final level of tank and riser at the end of the quarter cycle. It must be understood that all port areas in Mr. Johnson's formulas, as well as any figures for port area appearing in this discussion, assume a 100% coefficient of discharge, so that the actual ports when built must be increased to allow for losses.

The results are given in Table 3, together with those obtained by the formula, for the sake of comparison.

TABLE 3.

Case.	Size of port, a_0, in square feet.	Surge, y_1, with port $= a_0$, in feet.	Best size of port, a, in square feet.	Surge, y_1, with port $= a$, in feet.	Surge, y_1, by formula, in feet.	Percentage of increase of surge over result by formula.
S	8.97	18.20	8.1	17.51	17.35	0.9

The results obtained by formula and those computed by arithmetic integration with a port area equal to a_0, as well as the best size of port, were plotted together for comparison, and are shown in Figs. 5, 6, 7,

Mr. Taylor.

and 8. Only the riser levels are shown, as they alone affect the regulation directly. In all cases the tank and riser levels coincide at the beginning and end of the quarter cycle.

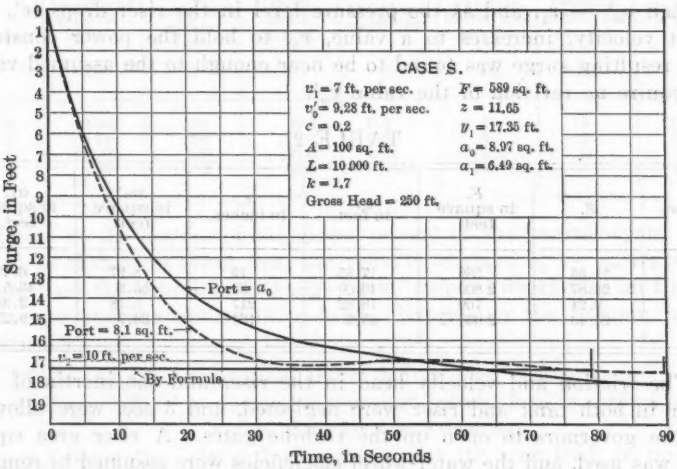

FIG. 5.

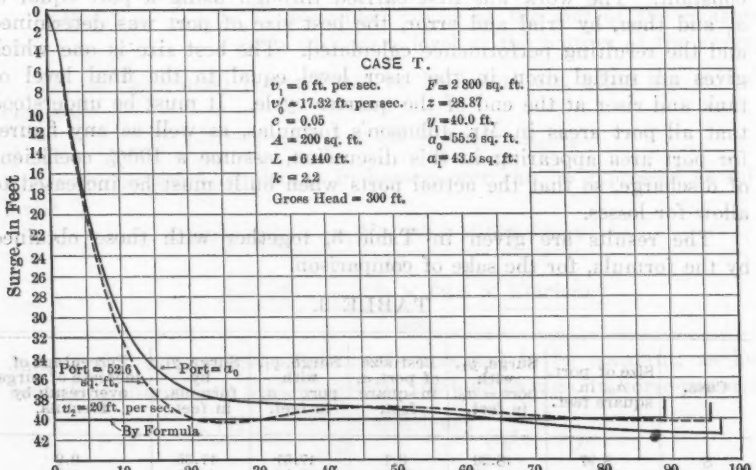

FIG. 6.

How closely the formulas approximate the performance with the correct size of port can readily be seen from the diagrams. In Cases S, T, and U, they almost exactly agree, and in only one instance, Case V, do they differ by as much as 2 per cent. In computing this

particular case, if the results of the formula are revised to be identical with the conditions of the arithmetic integration, making $v_2 = 24.10$ instead of 24.00, y_1 will be found to be 25.45 ft. instead of 25.2 ft., so that the computed result really only exceeds that obtained from the formula by less than 4% instead of 5% as given in Table 3. Looking at it in another way, if the surge, y_1, in the formula is made equal to that

Mr. Taylor.

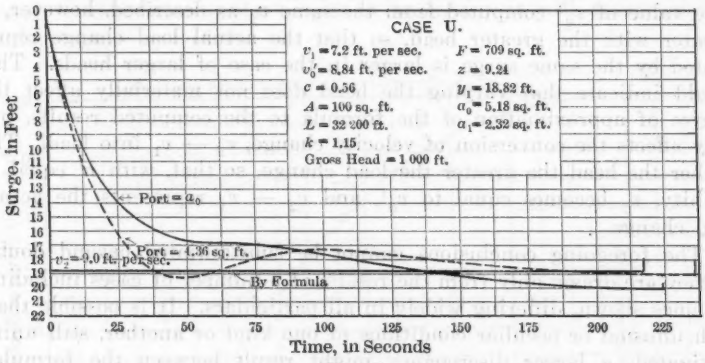

FIG. 7.

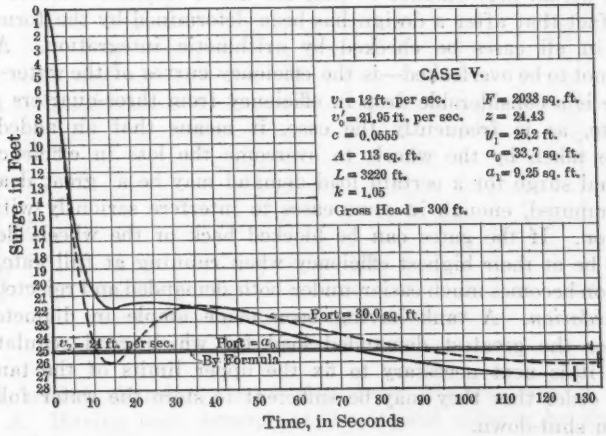

FIG. 8.

obtained by the arithmetic work (26.45 ft.), other values remaining unchanged, the actual load change given by the formula will only exceed the computed load change by 1.5 per cent. This difference is inappreciable when it is remembered that, in the first place, the load change and the value of c for which a tank is designed can only be estimated. This indicates that, as we approach dead-beat stability conditions, or values of k near unity with large load changes, where the difference

Mr. Taylor.

between the theoretical ports a_0 and a_1 is large, the formula drifts slightly away from the actual results. In the other direction, with values of k greater than 1.2 and velocity changes of 10% or more it has been found that the two methods practically coincide. The effect of assuming a larger head was tried in Case S, 650 ft. instead of 250 ft., and the resulting surge was computed as substantially the same. The value of v_0^1 computed from the same v_2 as described, however, is greater with the greater head, so that the actual load change represented by the same surge is larger in the case of larger heads. This would indicate that varying the head does not materially affect the degree of approximation of the formula to the computed results, but only affects the conversion of velocity change, $v_2 - v_1$ into load. The higher the head the greater the load change, so that, with H equal to infinity, v_2 becomes equal to v_0^1, and $v_2 - v_1$ represents the actual load change.

The foregoing conclusions cannot be substantiated beyond doubt, as they are drawn only from the results of a number of cases including the ones shown, differing widely in all particulars. It is possible that, with unusual or peculiar conditions of one kind or another, still uninvestigated, a larger discrepancy might result between the formulas and the actual performance so that too much emphasis cannot be laid on the fact that after a design has been determined by the formulas it should in all cases be checked by arithmetic integration. Another point—not to be overlooked—is the efficiency curves of the water-wheels. If there is a considerable drop in efficiency from three-quarters gate to full gate, as is frequently the case, it means that an added draft must be taken by the wheels to overcome the loss in efficiency, and the actual surge for a certain load demand may be a great deal more than computed, enough in some cases to interfere seriously with good regulation. If the gates can be blocked back or the wheels designed so as to be at their highest efficiency when running at full gate, surge regulation becomes much easier under both demanded and rejected loads.

Retardation.—A tank having been made ample in diameter and depth for the greatest demanded load for which good regulation is desired, it is next necessary to fix the upper limits of the tank and riser in order that they may be sufficient to store the water following a sudden shut-down.

Although the results desirable to attain under demanded load are largely a question of judgment and experience, those due to loads dropped are quite definite. Complete, sudden shut-downs are likely to occur on any plant, on account of line accidents and short circuits, so that the tank should be designed to handle the water if the full plant load is suddenly rejected. The only questions left to judgment are the maximum velocity occurring in the pipe line and the quantity of water likely to escape through relief valves and by water-wheel leakage.

Mr. Taylor.

There is for every specific power development a critical conduit velocity which requires the maximum height of tank. This is shown by Mr. Johnson in Formulas (36), (37), and (38). In some instances this critical velocity, which gives the maximum height of surge, happens to be less than, or not much greater than, the maximum full load conduit velocity. In such cases the critical velocity should be used in determining the height of tank, for it will assure absolute safety against overflow.

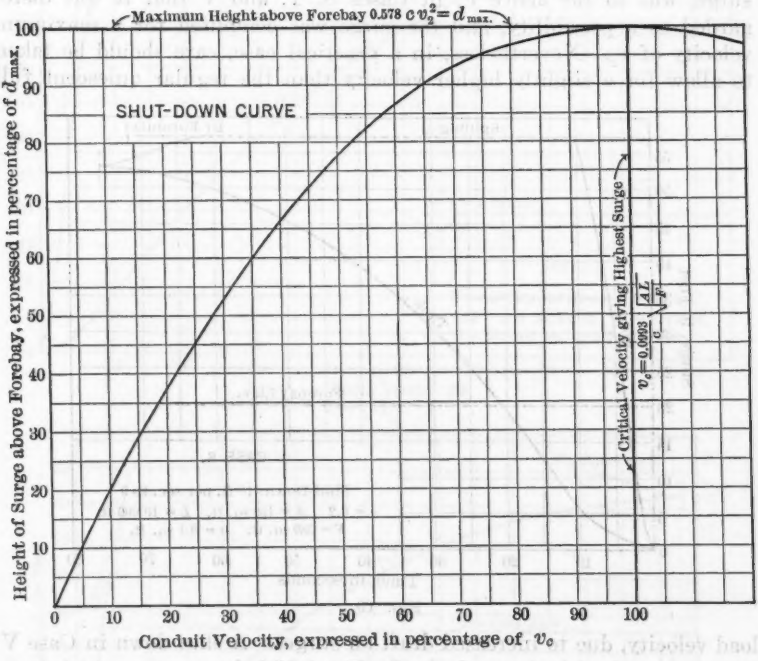

FIG. 9.

A useful shut-down curve has been plotted, and is shown in Fig. 9. Having once determined the critical velocity by the formula, $v = \frac{0.0993}{c}\sqrt{\frac{A\ L}{F}}$, which is merely Formula (36) in a more simple form, the height of surge to be expected at any other conduit velocity can be picked off graphically without additional computation. The height to which the water will rise, in case there occurs a higher conduit velocity than expected, or the effect of varying the assumption as to the value of c, can be determined with quite a saving of time by the use of this curve.

Mr. Taylor.

The great danger to be avoided in computing shut-downs is an error in the assumption of the coefficient, c, which, if smoother than figured, will cause the water at quiescent full load to stand higher and therefore attain a higher surge level than contemplated. For this reason, it is always better, when considering rejected loads, to use the smallest value of c that it is reasonably possible to expect.

The four cases previously referred to under acceleration were also computed for shut-down. The critical velocity giving the highest surge, was so far above v_2 in Cases S, T, and V that it was disregarded as a possibility, and the surge was computed for a maximum velocity of v_2. Nevertheless, in a practical case, care should be taken to allow for a slightly higher velocity than the regular quiescent full

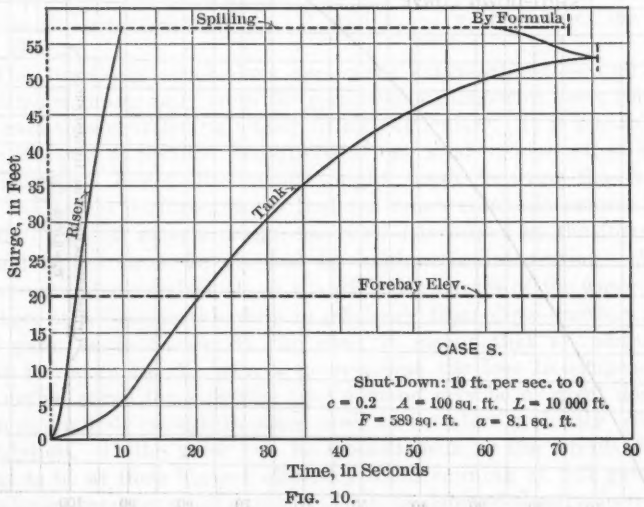

FIG. 10.

load velocity, due to increased draft on surges. A shut-down in Case V was computed with the critical velocity of 23.9 ft. per sec., which happened to be slightly less than v_2. It will be found by trial that, provided c is not made smaller, or the area of tank or conduit changed, no variation in velocity or length of pipe line will result in a higher surge level.

The heights of riser and tank for these four cases were first obtained by Formula (31), solving for the value of y_1 and using F as determined for demanded load. This height, y_1, was adopted for the riser, and the performance was computed by arithmetic integration. The results are shown graphically in Figs. 10, 11, 12, and 13, and the dotted line indicates the time during which the riser was spilling and represents also the height of surge as computed by the formula. The added

back pressure due to the weir height on the top of the riser when spilling, and the inertia and velocity head in tank and riser were neglected. Leakage through the wheels or discharge through relief valves was not considered. Mr. Taylor.

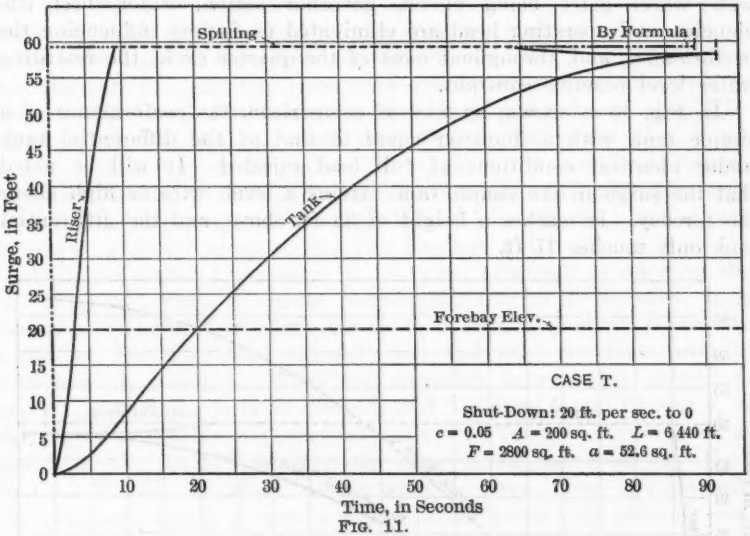

FIG. 11.

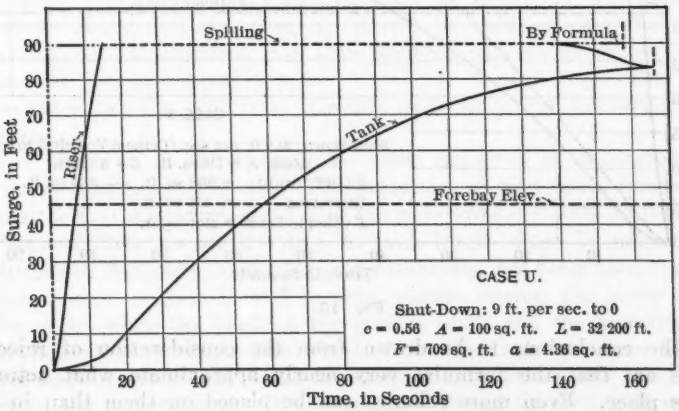

FIG. 12.

In every case the mathematical formulas lean toward the side of safety, giving a somewhat higher tank and riser than necessary. What actually takes place, however, in a shut-down, agrees so nearly with the premises of the theoretical formulas that it is a question in the

Mr. Taylor.

writer's mind whether they may not give results fully as close to what really takes place as those derived by arithmetic integration, unless the latter is computed in very small increments of time, and inertia. Velocity head and weir heights are taken into consideration. The water-wheel gates being closed, governor action, water-wheel efficiencies, and operating head are eliminated as factors influencing the performance, and, throughout most of the quarter cycle, the retarding water level remains constant.

In Fig. 13 is shown, by way of comparison, the performance of a simple tank with a diameter equal to that of the differential tank under identical conditions of full load rejected. It will be noted that the surge in the simple tank attains a level twice as high above the forebay. It reaches a height of 35 ft. above, and the differential tank only touches 17 ft.

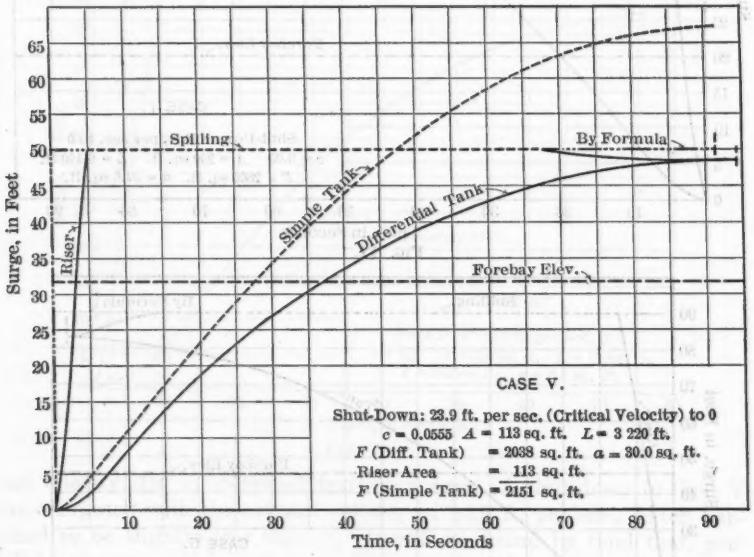

FIG. 13.

The conclusions to be drawn from the consideration of rejected loads are that the formulas very nearly approximate what actually takes place. Even more reliance can be placed on them than in the case of demanded loads. It is the writer's opinion that in the ordinary case they could be relied on to determine the design without further checking; yet, as there is a remote possibility that with certain peculiar conditions a discrepancy might appear, it is advisable to use some form of check or allow a factor of safety in extra height.

Mr. Taylor.

Ports.—The question of ports is very interesting as well as important, for the whole differential principle depends for its success on the choking action of the port. Pressure level changes following a load change are directly affected by the size of the port. Through it must flow the water to keep the riser level from dropping too far on demanded loads or rising too high on ordinary loads rejected.

In order to treat the subject mathematically, Mr. Johnson assumes that the port just supplies or receives enough water from the tank to keep the riser level stationary. To do this it must change size. The variation may be large or small, depending on the values of c, k, v_2, and v_1. It is largest for values of k near unity and load changes equivalent to more than 20% velocity change, and small for large values of k with any load change. It also increases as c and v_2 are increased, and *vice versa*, to zero as c becomes zero.

This fact makes it necessary to use some judgment in selecting the size of port. When a simple unchanging port is to be used, it is desirable to have it of such size as to approximate most nearly the action of the theoretical variable one, and hold the riser level as stationary as possible. When the variation between the values, a_0 and a_1, is small, as it is in Cases S and T (Figs. 5 and 6) size a_0 is quite good enough for all practical purposes. The best size of port, as shown by the dotted line, does not show much improvement. Even in Case V (Fig. 8) where the variation is large, there is little need for refinment unless to save a foot or so of surge. In general, however, when the variation is large, a trial by arithmetic integration should be made, and the area, a_0, should be reduced somewhat for better results. A rule that may save needless trial computation is to assume the port area equal to $a_0 - (0.1 \text{ to } 0.3) \times (a_0 - a_1)$, using the factor 0.3 when the difference is small, varying to 0.1 for large differences.

The reason a_0 so often cannot be much improved is illustrated by the curve shown in Fig. 14. The variation of port area necessary during the first quarter cycle to hold the riser level perfectly stationary has been plotted against the drop in tank level. Case V, under the conditions of demanded load discussed previously, has been used. Most of the change in area, it will be seen, occurs during the latter part of the cycle, when the head on the port is small and the quantity of water necessary to supply the wheels from the tank has been much diminished. During this period a variation from the theory has little effect on the performance. It is important during the first half cycle, when the port is discharging large quantities of water, that its actual size should not be far from the theoretical. The curve shows that during this period the theoretical size does not depart to any great extent from the original area, a_0, and, for this reason, a_0 will often suffice for all practical purposes.

Mr. Taylor.

The performances obtained with the use of various sizes of ports for the same conditions of velocity and load change were computed for Case S, and are shown graphically in Fig. 15. This diagram gives a clear conception of exactly what will take place in any specific case, if the port be made too large or too small. The sizes used range from an area large enough to allow free flow with no differential action to a port of 4.98 sq. ft. area or 0.555 a_0. With too small a port, the surge

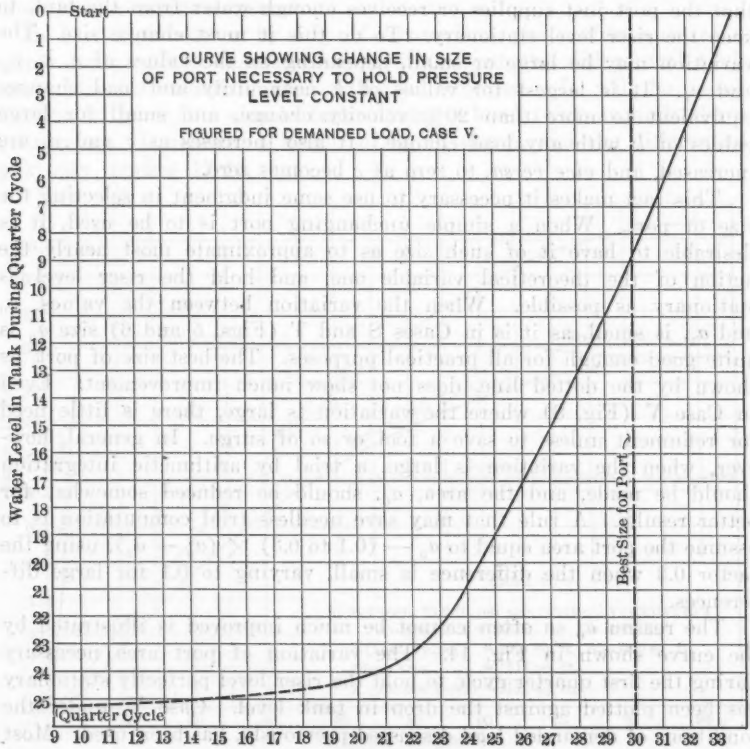

FIG. 14.

is increased on the first dip in riser level, there is more differential action, and at the end of the quarter cycle the water is much nearer the gradient level. Furthermore, if the performance were carried beyond the quarter cycle, the surging would be found to die out more quickly than with larger ports. With ports too large, the first dip disappears, and the water level at the end of the quarter cycle is drawn down, causing not only an excessive surge, but a long continuance of the disturbance following a single load change. The minimum surge

Mr. Taylor.

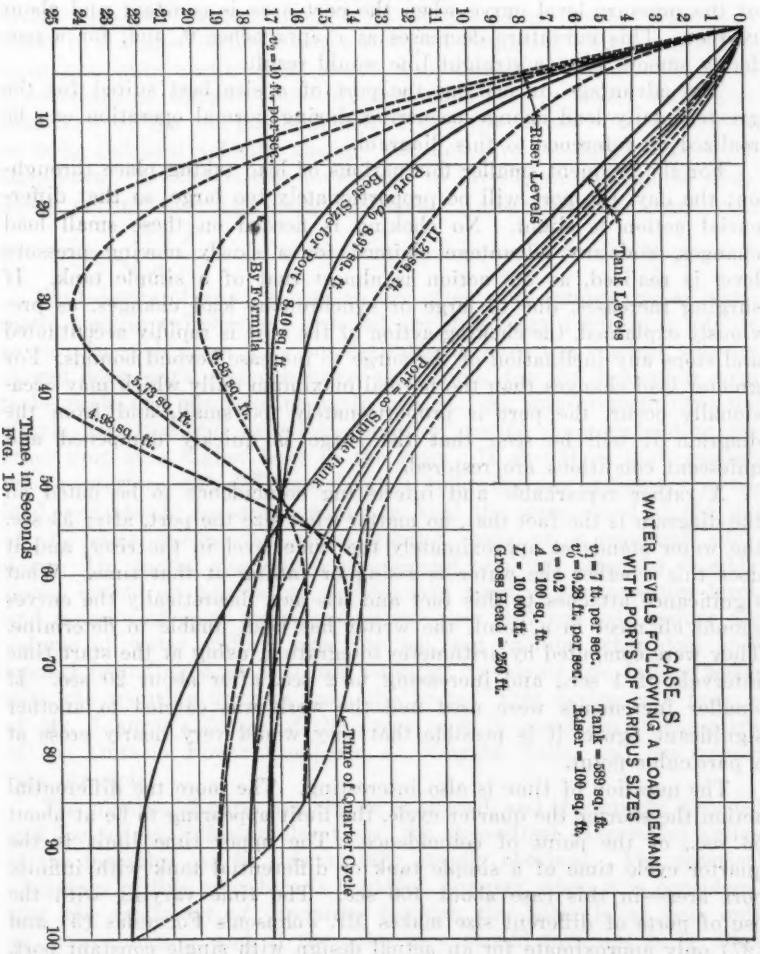

Fig. 15.

Mr. Taylor.

occurs when the first dip in the riser level is equal to the final drop in tank and riser. The port area of 8.1 sq. ft. very nearly fulfills this condition, and is, therefore, the best size of port for the load change under consideration. The slight piling up of the water in the riser between the lowest points of surge always occurs, and is characteristic of the pressure level curve when the port area is constant and about correct. This curvature decreases as c approaches 0, and, for a perfectly smooth pipe, a straight line would result.

The advantage of making the port of a size best suited for the greatest daily load change occurring during normal operation can be realized by reference to this diagram.

For the frequent smaller fluctuations of load taking place throughout the day, the port will be proportionately too large, so that differential action is slight. No choking is needed on these small load changes, and any advantage claimed for a slowly moving pressure level is realized, as the action is almost that of a simple tank. If surging increases, due to large or synchronous load changes, as previously explained, the choking action of the port is rapidly accentuated and stops any inclination of the surge to increase beyond bounds. For greater load changes than the normal maximum daily which may occasionally occur, the port is proportionately too small, and from the diagram it will be seen that the surge is quickly dampened and quiescent conditions are restored.

A rather remarkable and interesting coincidence to be noted on the diagram is the fact that, no matter what size the port, after 53 sec. the water stands at approximately the same level in the riser, and it does this whether the water is rising or falling at that time. What significance attaches to this fact and whether theoretically the curves should all meet in a point, the writer has been unable to determine. They were computed by arithmetic integration, using at the start time intervals of 1 sec., and increasing to 2 sec. after about 20 sec. If smaller increments were used and the work was carried to another significant figure, it is possible that they would very nearly cross at a particular point.

The question of time is also interesting. The more the differential action the shorter the quarter cycle, the limit appearing to be at about 53 sec., or the point of coincidence. The upper time limit is the quarter cycle time of a simple tank or differential tank with infinite port area—in this case about 100 sec. The time varying with the use of ports of different size makes Mr. Johnson's Formulas (3) and (27) only approximate for an actual design with single constant port. The extent of the departure from the actual time may best be judged from Figs. 5 to 8, which seem to indicate a variation of not more than 10% in extreme cases. As a knowledge of the exact time is unimportant, the formulas are close enough for all practical use.

Mr. Taylor.

Thus far, only port areas determined for demanded loads have been considered, as in nearly every case this requirement for good regulation fixes the size of port. One error, however, must be guarded against, that of making the port area too large for shut-down conditions and thus causing the riser level to draw down during the quarter cycle, with the accompanying loss of retarding head. This will result in a higher ultimate surge than contemplated. Such a predicament can only occur when severe and unusual requirements make it necessary to compute suddenly demanded velocity changes of more than 50% of the full-load velocity. For large values of k, even a 70 or 80% full-load velocity change will not give too large a port for shut-down. A safe course, however, is to investigate a complete shut-down performance by using arithmetic integration in every case where $c\, v_2 \sqrt{\frac{2\, g\, F}{A\, L}} + \frac{1}{10}$ is greater than $2\, r$ (see Formula (34)).

Shut-downs of any description are often only temporary, as automatic electric switches trip out and are closed again within a minute or so. In such cases it is not desirable to have the conduit velocity slowed down with as much haste as possible, for the demand is soon to be made and the velocity again needed. An improvement over the simple port that will help this condition can be made by adding another port at a higher level in the riser. It should be high enough not to interfere with differential action following any ordinary rejected load, and should be small enough to hold the water level at the top of the riser during the entire quarter cycle of a complete shut-down. On partial shut-downs this second port will often be of additional benefit in preventing unnecessary rises of the pressure level, and a series of small ports around the riser will not only reduce the volume of water spilling over the top, but cushion what does spill against pounding down into the tank, by traversing the falling water with the spouting streams from the ports. This device is a feature of Mr. Johnson's design of the surge tank in operation at the plant of the Ontario Power Company, at Niagara Falls, and has proved very beneficial.

The number of ports can also be increased, and if properly designed and located at different elevations, the theoretical differential action of the formulas can be substantially exactly obtained. The practical advantage of this procedure is doubtful, however, when it is considered that the coefficient of discharge through the holes is at best only an approximation, and, if the value of c should turn out to be other than expected, the refinements might result in an actual detriment to differential action.

CINDER CONCRETE FLOORS.

Discussion.*

By Messrs. Edgar Marburg and Guy B. Waite.†

Mr. Marburg.

Edgar Marburg, M. Am. Soc. C. E. (by letter).—In the writer's judgment, the validity of the author's contention, that a design in which cinder concrete is utilized should be governed by rational formulas and prescribed working stresses for the materials involved, cannot successfully be brought into question, provided the design itself is of such a character as to admit of satisfactory analysis, and the requisite empiric data for the unit stresses are available. In the consideration of this important, though essentially simple matter, the discussion should not be befogged by the introduction of irrelevant issues, such as the admittedly variable character of the material and the unsatisfactory conditions as to inspection by which its use is frequently, if not usually, attended. Inadequate inspection cannot reasonably be urged in support of adherence to unscientific methods in relation to the use of this material any more than in relation to any other material. Scientific and therefore economic design is, broadly speaking, impossible in any field of construction without rigid inspection in its execution. If the actual loads on building floors approximated more nearly to those prescribed by building codes, the many failures that would probably have resulted would long ago have enforced the lesson of adequate inspection. That circumstance, however, has no bearing whatever on the merits of the basic question under discussion. It may be, and probably is, true, that cinder, no matter how carefully inspected, is a much more variable product than stone or gravel. If so, that circumstance should be recognized by the selection of correspondingly conservative working

*Continued from August, 1914, *Proceedings*.

†Author's closure.

Mr. Marburg.

stresses in accordance with a principle as old as engineering itself. Such working stresses having been fixed, designs susceptive of rational analysis should be based on suitable formulas and not on tests, except in so far as tests may be made to establish the reliability of the premises —both as to theory and working stresses—governing the design, so that these may then be applied with confidence to other designs of the same general character, but differing as to dimensions, and as to the relative quantity and distribution of the material. To depend wholly on tests, under the conditions stated, would mean a reversion to empiricism unworthy of serious consideration in modern engineering. This statement is just as applicable to cinder concrete as to any other material of construction.

If, on the other hand, the proposed design of which cinder concrete is to be an element is not demonstrably susceptive of rational analysis, only two courses are open: either to prohibit its use, or to have recourse to tests. That statement, too, is just as applicable, however, to stone or gravel concrete, or to any other material, as to cinder concrete. An attempt at differentiation in this connection at the expense of cinder concrete is so manifestly unwarranted that arguments to the contrary would seem superfluous. If such indeterminate designs are to be used, precisely the same precautionary considerations are applicable to cinder concrete as to any other material used under such conditions, namely, that the same care as to the selection of material, workmanship, and inspection should be applied to the construction itself as was applied to the particular elements subjected to test. Furthermore, the information yielded by such tests cannot safely be applied to other similar designs varying materially from those under which the tests were made, as to general dimensions and relative quantities and distribution of material,—that being the well-recognized limitation of empiric, as distinguished from rational methods.

To sum up, at the risk of reiteration, there is, in the writer's judgment, no inherent ground for making any distinctions whatsoever between the general considerations governing the design of reinforced concrete, whether the aggregate be stone, gravel, slag, or cinder. Whether the use of cinder concrete should be permitted where the strength element is an important factor; whether the prescription of proper working stresses would tend to militate against the economic use of this material; and whether its use, at least under certain conditions, should be avoided by reason of the tendency of the embedded steel to corrode, are questions with which the writer is not at present concerned. These questions have no bearing, however, on the fundamental principles which he has endeavored to emphasize, and their discussion in that connection would only tend to becloud the author's basic contention, which, in the writer's judgment, is incontrovertible.

GUY B. WAITE, M. AM. SOC. C. E. (by letter).—The purpose of this paper is: Mr. Waite.

1.—To show that cinder concrete is being used extensively in engineering construction;

2.—To present the fact that, in many cases, this material is not being used in accordance with well-defined engineering principles; and

3.—To obtain discussion among engineers with a view of either having its use included in the category of engineering, or of finding the reason that it should not be so placed.

So far as the writer is able to comprehend the discussions, nothing has been produced to give reasons for not designing cinder concrete according to unit stresses, as required of stone concrete.

The writer agrees with Mr. Marburg that no successful argument can be made for the arbitrary use of reinforced cinder concrete. His position, as head of an institution of engineering, and his connection with the American Society for Testing Materials, entitles him to recognition as an authority on this subject.

The only substitute for unit stresses suggested by any who have discussed the paper was a recommendation for more extensive testing. Of course, with sufficient testing to determine the proper working stresses, it would not be engineering to continue to test for every possible variation in spans, thickness of slabs, and difference in loadings.

Mr. Strehan makes several criticisms, among which are the following:

1.—That "the writer fails to find any plausible basis in the paper on which to establish constants for calculation and unit stresses for design;"

2.—That tension in the cinder concrete is omitted;

3.—That the difference between the conditions of cinder concrete between steel beams and the monolithic condition of all the reinforced concrete is not shown by the writer;

4.—That the trussing effect of side arches on the carrying capacity of any particular arch was overlooked in the paper; and

5.—That the continuous action of reinforcement anchored over the steel beams was ridiculed.

The matters referred to in Criticisms 3, 4, and 5 were mentioned on pages 894 and 899,* and were evidently overlooked by Mr. Strehan. This was the explanation given for the great loads carried by the test arches.

* *Proceedings*, Am. Soc. C. E., April, 1914.

Mr. Waite.

In answer to Criticism 1, the writer would refer to Table 2* giving the unit stresses adopted for this material by several large cities which have placed it on an engineering basis. There is also presented the first of a series of tests made by the Bureau of Buildings of New York City and Columbia University. Further, the writer has his own views regarding its proper working stresses; however, it was not the purpose of the paper to open up side issues for critics to utilize in misleading readers from the real purpose, namely, the establishment of some kind of unit stresses.

In his official connection with the Bureau of Buildings of New York City, Mr. Strehan took part in the tests recorded in Table 2. He refers in his discussion to a coming paper in which he will probably give more up-to-date information on the properties of cinder concrete than is now available. Therefore, it should become his duty as a public official—not the duty of the writer—to assign the exact proper units to be used for New York City. The writer's paper was on the general subject, and the tabulations cover almost every possible assumption.

As to Criticism 2, the writer pleads guilty of the crime of failing to consider tension in the concrete of the reinforced cinder concrete slabs. The report of the Special Committee on Concrete and Reinforced Concrete, which was referred to on pages 913 and 914,* does not recognize tension, even in stone concrete. The stresses developed by the approved loads on cinder concrete, shown on those pages, make such an allowance (or even the talk about it) ridiculous.

As to Criticism 3, it was pointed out that the cinder concrete between steel beams was substantially cut in two and could not act in the certain and continuous manner of monolithic reinforced stone concrete; and for that reason, if for no other, greater stresses should not be allowed on the former than on the latter.

Referring to Criticism 4, Mr. Strehan admits that the outside spans of floor-slabs have not the same capacity as interior slabs, that is, those which have adjoining construction on both sides. As mentioned in the paper, the adjoining slabs thrust against the interior slab. Now, in the test slabs of the constructions discussed in the paper, Figs. 3 to 7,* there were adjoining slabs; but in a large proportion of the slabs in buildings, one side (the outer side) has no slab adjoining to act against thrust.

In discussing Criticism 5, the writer must refer to experiences he has had with light reinforcing members used in the same manner as the wire mesh for the purpose of securing a continuous reinforcement. In 1900 he began the erection of reinforced concrete. His first contract was for cinder concrete floor-slabs located (as generally used in hotel and apartment-house construction) on the lower flanges of

* *Proceedings*, Am. Soc. C. E., April, 1914.

the steel supporting beams. The reinforcement consisted of small thin steel bands drawn continuously over the steel beams and bent down in the central part to reinforce the bottom of the concrete slabs. The metal was kept straight and tight, with the object of securing a continuous action. It was found that in this condition the tamping of the concrete jarred the reinforcement and jerked it in the adjoining slabs to such an extent that the bond was disturbed and cracks appeared in the concrete over each piece of metal. Mr. Waite.

After trying out the system thoroughly, it was abandoned because no practical way of making it continuous could be found. The manner in which the wire mesh and the light reinforcement have been and are being used for the foregoing conditions may be described as follows: The wire or other metal is drawn over the steel beams and then stamped down on both sides and left with sufficient slack to prevent the jerking of the reinforcement, previously mentioned.

An examination of the work actually done in buildings will show much of the reinforcing wire, referred to by Mr. Strehan as being anchored over the beams, simply lying loose on top of them. In this condition there cannot possibly be any continuous action, because the strain comes on the center of the slab before the metal over the supports is drawn tight. All that can be expected of the reinforcement anchored over the beams, is to hold the slab suspended after it has broken in the center. Of course, in a single test slab, sufficient time and pains can be taken to insure continuous action and obtain illusionary results.

Mr. Strehan does not agree with the writer that one kind of reinforcement is as good as another. The writer would modify this statement, to withstand criticism, by saying that what was really meant was that, any forms of steel sufficiently embedded in concrete for the adhesion to develop the full section of the metal will give substantially the same results. This fact was shown for stone concrete in tests by A. N. Talbot, M. Am. Soc. C. E., several years ago, and the tests in Table 4* for cinder concrete seem to show the same result.

The writer referred to the subject of the capacities of various kinds of reinforcement because the arbitrary manner of using cinder concrete has led to all kinds of misrepresentations by sellers of reinforcements. Some have obtained approvals with much less reinforcement than others; all make claims of some peculiarity in their form or kind of material, which makes it superior to all others. In the proposed Building Codes of 1912 and 1913 of New York City (Table 1),* this recognition of superiority was to have been specified in the law.

On account of the seeming protection, by the arbitrary use of the construction, large industries have been built up. It is the writer's

Proceedings, Am. Soc. C. E., April, 1914.

Mr. Waite. belief that some of these industries have been the father of many of the agitations for new building codes.

Several who discussed the paper referred to the corrosion of steel embedded in cinder concrete. Some seem to think cinder concrete should be restricted, because there is no certainty that the steel is protected against corrosion. As the situation stands, these arguments for restriction are too late; cinder concrete is already used extensively, and the object of this paper is to have it used in a rational manner.

The subject of the corrosion of steel, however, is vital, and should be better understood. It is the writer's experience that the average quality of hard coal cinders mixed in the proportion of 1:2:5, made wet, and tamped thoroughly, will sufficiently coat the surface of the steel with neat cement wash to protect it thoroughly and permanently from corrosion. When the grade of cinders runs too coarse to fill the voids, the concrete is porous, in which case, unless the steel is first coated with cement wash, the concrete is likely to contain air holes extending to the bare steel.

Mr. Himmelwright regrets the fact that the writer did not include the discussion of other forms of cinder concrete than the ordinary plain reinforced construction. The construction discussed in the paper is that which has automatically displaced those referred to by Mr. Himmelwright, and—perhaps it is not exaggeration to say—is the form of construction in universal use, where competition is allowed. The writer may lament this as much as Mr. Himmelwright, but, knowing the facts, he did not wish to confuse the subject by the introduction of constructions so far removed in relationship that it would be useless to attempt to make a formula to include them all.

In defence of the writer's rational treatment of the subject and of the general tabulations, to cover the use of almost all constants, he begs to state that this was done principally because, in past discussions, before aldermanic committees, etc., the unit-stress idea has been ridiculed, and more than one member of the Society has scouted the idea that a rational treatment was practical.

It is hoped that engineers will awaken to their own interests by insisting that cinder concrete, when used as an engineering construction, shall be elevated from the field of irresponsible contractors, referred to by several in their discussions, to the field of Civil Engineering.

THE POSSIBILITIES IN BRIDGE CONSTRUCTION BY THE USE OF HIGH-ALLOY STEELS.

Discussion.*

By J. A. L. Waddell, M. Am. Soc. C. E.†

Mr. Waddell.

J. A. L. Waddell, M. Am. Soc. C. E. (by letter).—The writer's hearty thanks are herewith extended to all who have done him the honor to discuss this paper, and he is specially gratified by the appreciative reception which it has met at their hands.

In this résumé he will treat only of those topics on which a disagreement of opinion has been expressed, or those which afford data for a further development of the subject. Although many of the points raised in several of the discussions are foreign to the subject at issue, dealing with bridge designing and construction in general, nevertheless, the writer has answered such points to the best of his ability and according to his experience.

Replying to the suggestion by Mr. Le Conte, which has been offered also by Mr. Molitor, that experiments be made with aluminum as an alloy material for bridge steel, the writer regrets that hitherto he has been unable to collect any authentic information concerning aluminum-steel alloys; nor did he pay much attention to the possibilities of such a combination on account of the previous high price of aluminum. With a present price of only 20 cents per lb., however, and the possibility of attaining an elastic limit of 100 000 lb. per sq. in., the conditions are changed materially, making the expenditure of much time, effort, and money on the necessary investigation well worth while. Mr. Le Conte stipulates that before adding the cake of aluminum to the molten steel, the latter must first be "'thoroughly purified' and its elastic limit raised thereby to 60 000 lb. per sq. in." How this is to be done, he does not say. If steel, high in carbon,

* Continued from September, 1914, *Proceedings*.
† Author's closure.

Mr. Waddell.

produced by the electro-metallurgical process, were used, such a great elastic limit might possibly be attained; but, judging from what was told the writer by some gentlemen interested in titanium, the use of that metal as a scavenger does not materially raise the elastic limit or the ultimate strength of the steel, its effect being mainly to make the product more uniform and reliable.

It is evident that much experimenting would have to be done in order to determine how best to produce an aluminum-steel alloy suitable for bridgework.

Mr. Le Conte's estimate of 2.5 cents per lb. for the excess cost of the manufactured alloy appears to be liberal enough; for purified steel smelted by the electro-metallurgical process, as claimed by its French producers, costs only 0.9 cent per lb. more than carbon steel, which amount added to the cost of the aluminum, would make the excess only 1.5 cents per lb., leaving 1 cent per lb. to cover a possible slightly increased cost of rolling the plates and shapes and the extra profit which, doubtless, would be insisted on by the manufacturers on the plea of expense due to innovation from current practice.

All that Mr. Petinot has said in his discussion concerning the use of titanium in the manufacture of steel is of the greatest interest and value to the Engineering Profession; but it is to be regretted that he omitted to state a number of facts of importance which he mentioned to the writer during a long conversation on the subject held a day or two previous to the presentation of the paper to the Society. At the moment of writing, the writer cannot recall the omitted information, except only that (as he indicated in the comment on Mr. Le Conte's discussion) titanium purifies and makes much more reliable the steel with which it is alloyed, but does not increase to any great extent the elastic limit or the ultimate strength.

The writer is glad to note the corroboration of the claim made by Mr. T. L. Willson to the effect that it is practicable to manufacture satisfactory nickel steel by the addition of ferro-nickel instead of the pure metal. It seems strange that Mr. Willson has not seen fit to take part in the discussion of this topic; for he has been given several opportunities to do so.

As, according to Mr. Petinot, the cost of purifying steel by the use of titanium amounts to only 25 or, at most, 50 cents per ton, it would seem advisable, after his claims have been well established, for the Profession to insist on its use in the manufacture of all carbon steel for bridgework.

The writer desires to emphasize forcibly the remarks of Mr. Moisseiff concerning the necessity of proportioning all highway bridge floors so as to carry properly the heavy concentrated live loads imposed on them by automobile trucks, and concerning the inefficiency of buckle-plates to support pavements subject to such loads. Every

Mr. Waddell.

bridge designer should take these statements to heart, and be guided thereby in detailing his floors for highway structures; for, no matter how remote or insignificant a highway bridge may be, it is within the realm of possibility that at any time it may have to carry heavy automobile trucks.

Concerning Mr. Moisseiff's warning about the greater distortions (and, therefore, greater secondary stresses) in bridge members when high-alloy steel is used: This is evidently well founded; but, on the other hand, the fact that the members are more slender in an alloy-steel bridge than in a corresponding carbon-steel structure offsets somewhat the injurious effects of the extra distortion. Moreover, in the best modern bridge engineering practice, the greater part of the maximum secondary stress on each main member is overcome by forcing a reverse secondary stress into the metal during erection.

Concerning the efficiency of nickel-steel rivets, the writer would refer Mr. Moisseiff to the discussions by Messrs. Hodge and Skinner at the meeting of the Society when the paper was presented, only a part of which has been recorded in print in Mr. Skinner's discussion. It seems from these discussions that even very long and large nickel-steel rivets can be driven satisfactorily in both shop and field. In alloy-steel bridges, as in carbon-steel bridges, it will, necessarily, be the practice to use much softer steel for rivets than for plates and shapes in order to make possible the cutting out of defective rivets.

Mr. Skinner's question as to the possibility of developing a super-strong alloy steel by subjecting finished members to heavy test loads at the shops, opens up a new subject. The writer thinks that such a practice might be feasible for eye-bars, in which the holes might be drilled small for testing and be enlarged after the bars are stretched; but that kind of manipulation could not well be applied in the case of compression members, unless they are all pin-connected, which construction, although possible, would involve many complications and difficulties in detailing.

Mr. Molitor's remarks concerning piping and segregation are both pertinent and timely; and it cannot be questioned that the manufacture of "high-alloy" steels for bridges should receive far better attention than that of the commercial carbon steel for such structures. Manufacturers object to any requirement that tends to prevent them from turning out their product quickly and in great quantities. One cannot blame them for this, because it is human nature to desire to make as great a profit on work as possible; but if engineers would insist on obtaining what they know to be necessary in order to secure the best results, and if they would make their clients pay a proper price for the improvement in manufacture, it should not be very difficult—at least not impossible—to effect important innovations in the art of bridge building.

Mr. Waddell.

It is this reluctance of the metal manufacturers to adopt innovations and to take special pains, which has prevented the Engineering Profession from having had at its disposal during the last five or six years a nickel steel for bridge building with a minimum elastic limit of 60 000 lb. per sq. in. A little extra care in the furnace manipulation and a moderate increase in the cost of shopwork are all that is necessary to provide such an alloy in as large quantities as may be desired; and the excess pound price for the finished material should only be in direct proportion to the actual excess cost of preparing the rolled sections and of manufacturing them into bridges.

In reference to the theory of segregation and piping, it is to be hoped that engineers will insist on metal manufacturers giving the "Liquid Forged Steel Process" a fair trial. If it be true that the use of this process by purifying the steel and by avoiding piping will raise the elastic limit and ultimate strength of the metal 20%, a most important advance can be made by its adoption in the attainment of a true high-alloy steel for bridge building.

The writer will have to take issue with Sir Bradford Leslie concerning the effect of impact on bridges. Sir Bradford appears not to believe that impact from rapidly moving live loads on bridges is an actuality. The writer knows that it is, for he has both seen and measured it on a number of occasions. In one series of experiments on spans as a whole (not on their individual members), he found increased deflections from motion varying from 20% for spans of 160 ft. to 50% for a span of 88 ft. It is true that the longer spans were pin-connected and of ancient design, and that the shortest one was of the riveted type and disgracefully detailed; nevertheless, other experiments of his on properly designed bridges all show more or less increased deflections due to motion. Again, a committee of the American Railway Engineering and Maintenance of Way Association has made many hundreds of determinations of impact on bridges; and its results are a matter of record.

Sir Bradford questions the writer's reason for assuming that long-span railway bridges will have, at least, two tracks. He would, indeed, be a short-sighted American engineer who, to-day, would counsel his client to build a bridge of very long span with a single track; although it would be quite legitimate to adopt the writer's patented expedient of designing it in such a manner that, in the future, duplicate trusses might be added so as to double its carrying capacity.

It is not a dread of wind pressure, as Sir Bradford supposes, which causes American bridge engineers to double-track their long-span bridges (for the width between trusses can be increased to any desired amount without providing an additional track), but because they recognize the fact that if the client can afford to spend a large sum of money for a railroad bridge, the traffic of the line should be great

enough to call for a double track, if not at present, at any rate in the near future. Mr. Waddell.

Mr. Fergusson's discussion is really based on the writer's former paper, "Nickel Steel for Bridges",* as it hardly deals at all with the question of using high-alloy steels. Moreover, Mr. Fergusson is apparently somewhat behind the times; for, in several instances, he questions established facts.

He says that "the use of nickel steel cannot be adopted, generally, as the best material for all classes of bridgework." All that prevents this to-day is the unwillingness of the manufacturers of bridges to adopt the innovation and to put a reasonable price on the product.

He says, also, that "carbon steels, for a tensile strength of 40 tons per sq. in., have advantages over nickel steels carrying low percentages of nickel." Any ordinary carbon steel having a minimum ultimate strength of 40 tons per sq. in. would be too brittle to use in bridge construction. It is true that, by taking special pains in its manufacture and drilling solid all the rivet holes, it might be practicable to use such high carbon steel; but it would be bad policy to do so when a nickel steel some 40 or 50% stronger is obtainable at a not entirely unreasonable price. Nickel steel having an ultimate tensile strength of 60 tons is more uniform and reliable than an ordinary carbon steel of 40 tons—at least, that is the writer's opinion, based on an extended experience with bridge metals.

Mr. Fergusson says "the testing of nickel steel during the process of manufacture is very complicated, the material is subject to great variations;" etc.

Such is not the writer's experience in the building of nickel-steel bridges, nor, unless he is greatly mistaken, is it that of Mr. Hodge or of other American engineers who have had occasion to build structures with that alloy.

Mr. Fergusson says:

"To use a nickel steel of very high tensile strength, chiefly to save weight in the bridge material—unless where the conditions are imperative—would seem to be extravagant, and even unwise. There must be risk in trusting to the highest limit of tensile strength of a manufactured steel which is known to be very variable."

In answer to this the writer would state that nickel steel is not "very variable", as can be seen by a systematic study of his inspectors' reports, which are published in Appendix A of the paper on "Nickel Steel for Bridges." Those records show clearly that the different kinds of nickel steel are just as regular in their elastic limits and ultimate strengths as the different kinds of carbon steel.

There is no more risk in "trusting to the highest limit of tensile strength" of nickel steel than in trusting to the highest limit of

* *Transactions*, Am. Soc. C. E., Vol. LXIII, p. 101.

Mr. Waddell.

tensile strength of carbon steel—moreover, it is not the highest limit which is adopted as a minimum in specifications, but one fairly close to the lowest limit, so chosen as to avoid the necessity for many rejections.

The writer wonders what Mr. Fergusson deems is the object of bridge engineers in ever using nickel steel for their structures, unless it be "to save weight in the bridge material." That is the sole *raison d'être* for its adoption.

Mr. Fergusson says: "The proportion of 3.5% of nickel, which he [the writer] gives, appears to be too low." For plate-and-shape steel this is as much as it is either profitable or advisable to use. Any greater percentage would add to the expense of the rolled metal and increase the cost of the shopwork. However, for eye-bars in which the amount of shopwork is small, it is economical to increase the percentage of nickel to about 4.25.

Mr. Fergusson says: "As he [the writer] does not mention carbon in his analysis, it may be presumed that he has eliminated it; surely this is a difficult operation in commercial manufacture?"

It certainly would be—but, unfortunately for Mr. Fergusson's deduction, the writer did not attempt to cut out the carbon—far from it. The great strength of nickel steel in bridgework is largely due to the fact that the addition of nickel permits of a substantial increase in the percentage of carbon. The nickel itself adds to the strength of the metal, but at the expenditure of considerable money; while the increase in the carbon content adds to the said strength without augmenting the cost at all. Surely Mr. Fergusson has failed to read with any care the paper on "Nickel Steel for Bridges"; for if he had done so, he would not have made such a blunder. The specifications for the various classes of nickel steel given in Table 4 of that paper call for the following compositions:

Ingredients.	Percentages.		
	Rivet steel.	Plate-and-shape steel.	Eye-bar steel.
Nickel	3.50 (3.25 to 3.75).	3.50 (3.25 to 3.75).	4.25 (4.00 to 4.50).
Carbon	0.15 (0.12 to 0.18).	0.38 (0.34 to 0.42).	0.45 (0.40 to 0.50).
Phosphorus	0.03 maximum.	0.03 maximum.	0.03 maximum.
Sulphur	0.04 maximum.	0.04 maximum.	0.04 maximum.
Silicon	0.04 maximum.	0.04 maximum.	0.04 maximum.
Manganese	0.6 (0.55 to 0.65).	0.70 (0.65 to 0.75).	0.80 (0.75 to 0.85).

Speaking of the strengths of nickel steels of varying percentages of nickel, Mr. Fergusson states that "the increase of nickel requires a decrease of carbon, together with an increase of manganese, otherwise, although the breaking load may be the same, the value of the elastic limit will fall rapidly." Within the limit of the writer's experiments,

Mr. Waddell.

which do not cover alloys higher in nickel that 4.5%, he has found that just the opposite condition exists; for increasing the carbon content raises both the elastic limit and the ultimate strength.

The writer does not claim that nickel steel having a greater percentage of nickel than 3.5 is absolutely unworkable in the shops; but that commercially it is so. On page 103 of the paper on "Nickel Steel for Bridges" will be found the following:

"Curiously enough, the superior limit of nickel steel for workability in bridge shops varies but little, if any, from the economic amount based on present prices of steel and nickel. For plates and shapes, which form the principal part of bridge superstructures, any materially greater percentage than 3½ renders the alloy too refractory for the various shop manipulations to which it would be subjected in manufacturing it into bridges, although superstructures built of steel still higher in nickel would be perfectly safe and satisfactory for operation."

If Mr. Fergusson will read the results of the investigations of Messrs. Carpenter, Hadfield, and Longmuir,* he will see the danger of using high percentages of nickel in bridge steel; for these gentlemen have demonstrated the existence of a "brittle zone" in nickel steels, beginning with a percentage of nickel lying between 4.25 and 5.0, and ending at 20. These investigations were referred to in the writer's former paper.

Mr. Fergusson points out what he claims to be "two disadvantages in nickel steel for bridgework:

"(*a*) The difficulty of welding, and working;
"(*b*) The necessity of keeping the carbon extremely low—under 0.20%—whereas the fatigue resistance of steel is increased enormously by raising the percentage of carbon."

To these criticisms the writer would reply as follows:

First.—Welding in bridgework is now a thing of the past, and has been ever since the days of wrought-iron bridges.

Second.—There is certainly more difficulty in manipulating nickel steel in the shops than in handling carbon steel there, but the extra cost is trifling, amounting to between 0.15 and 0.25 cent per lb. This is a bagatelle compared with the advantages gained by the use of the alloy.

Third.—There is no reason whatsoever for "keeping the carbon extremely low."

Fourth.—The fatigue of steel in bridges is now conceded by the leading American engineers to be entirely a myth. For many years it was a great bugbear to bridge builders; but to-day it is a well-known fact that there is no "fatigue" of metal unless the elastic limit is exceeded; and most of the reputable American bridge engineers

* *The Engineer* (London), November 24th, 1905.

Mr. Waddell.

aim to keep the actual intensities of working stresses in their structures down to about one-half of the elastic limit.

Answering Mr. de Broë's discussion, in reference to the price of steel: the writer assumed in 1907 that the average pound price for plate-girder spans erected was 4.0 cents; and to-day it is half a cent less, or 3.5 cents. Subtracting from this, as an average, 1.25 cents for freight and erection, would make the pound price, f. o. b. cars at the shops, 2.25 cents, which is about right. During bad times in the United States plate-girder spans can be bought for less than 2.0 cents per lb., f. o. b. cars at the works; but when times are very good, this figure is increased some 50% or more. Mr. de Broë's quotation of £13/10/0 per ton, as the highest price paid in England during the last few years for bridge superstructures, corresponds to nearly 3.0 cents per lb. The writer does not think that bridges can be manufactured in England as cheaply as they can in the United States, but admits that in this opinion he may be mistaken.

In regard to the question of impact brought up by Mr. de Broë, the writer has treated that subject already in his reply to Sir Bradford Leslie's discussion; but he would remark that although the recorded impact on that 40-ft. span at 45 miles per hour may truly have been zero, a lower velocity of train might readily have indicated a high percentage—such, at least, has been the experience of American engineers (among others the writer) in testing bridges for deflection under static and moving loads. The writer is quite convinced from a practical experience in the designing, building, examination, and testing of bridges, extending over a period of more than 33 years, that the use of proper impact formulas or curves is a necessity in truly scientific design.

He takes pleasure in complying with Mr. de Broë's request for "the more accurate formula" which he has evolved from the published tests of a commission of the American Railway Engineering and Maintenance of Way Association appointed to experiment on impact from moving loads on railroad bridges. The formula for coefficients is

$$I = \frac{165}{L + 150};$$

or, in terms of percentages, it is

$$I = \frac{16\,500}{L + 150},$$

where L is the length of span, in feet, covered by the moving load. The highest of the three curves in Fig. 28, prepared from this formula, gives the coefficient of impact for all spans between zero and 1 000 ft. At these limits, the coefficients are, respectively, 1.10 and 0.14.

The writer regrets that he cannot at the present writing give Mr. de Broë the name of the publication containing the results of

Mr. Waddell.

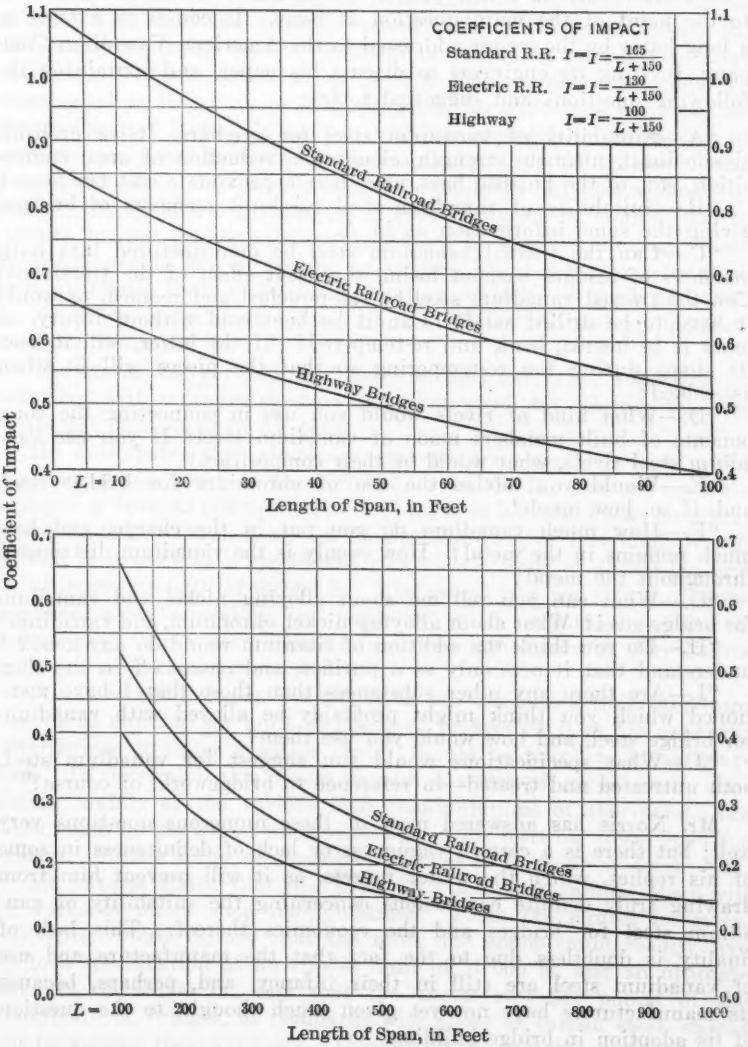

FIG. 28.

Mr. Waddell.

the impact experiments from which the foregoing formula was prepared.

The discussion by Mr. Norris is exceedingly valuable, being directly to the point of the main question at issue. It comes as a reply to a long letter by the writer addressed to the American Vanadium Company, inviting its engineers to discuss his paper, and containing the following questions and suggested topics:

"A.—Suitability of vanadium steel for eye-bars. Give probable elastic limit, ultimate strength, elongation, reduction of area, composition, etc., of the finished bars, also their approximate cost per pound.

"B.—Suitability of vanadium steel for built members of bridges, giving the same information as in A.

"C.—Can the treated vanadium steel be manufactured into built members of bridges without losing the great effect of the treatment? Can the treated vanadium steel be sub-punched and reamed, or would it have to be drilled solid? Can it be bent cold without injury, or must it be heated, bent, and re-tempered? If the latter, will it keep its shape during the re-tempering so that the pieces will fit when assembled?

"D.—What kind of rivets would you use in connecting the components of built members made of vanadium steel? If you use vanadium steel rivets, what would be their composition?

"E.—Would you advise the use of chromium for bridge steel, and, if so, how much?

"F.—How much vanadium do you put in the charge, and how much remains in the metal? How evenly is the vanadium distributed throughout the metal?

"G.—What can you tell me about alloying nickel and vanadium for bridge steel? What about alloying nickel, chromium, and vanadium?

"H.—Do you think the addition of titanium would do any good? I understand that it acts only as a purifier, and passes off in the slag.

"I.—Are there any other substances than those that I have mentioned which you think might profitably be alloyed with vanadium for bridge steel, and how would you use them?

"J.—What specifications would you suggest for vanadium steel, both untreated and treated—in reference to bridgework, of course?"

Mr. Norris has answered most of these numerous questions very well; but there is a certain vagueness or lack of definiteness in some of his replies, which the writer regrets, as it will prevent him from drawing truly definite conclusions concerning the suitability of vanadium steel for bridges and the economics thereof. This lack of finality is doubtless due to the fact that the manufacture and use of vanadium steel are still in their infancy, and, perhaps, because its manufacturers have not yet given much thought to the question of its adoption in bridge building.

It will be well to take up each of the preceding points and questions consecutively, and see what has been answered and what remains to be determined.

Mr. Waddell.

A.—It is evident from the discussion that vanadium steel is eminently fitted for the manufacture of eye-bars. The elastic limit for full-sized, chrome-nickel-vanadium bars varied in the tests from 63 280 to 80 480 lb., and the ultimate strength from 93 500 to 99 800 lb., the results depending on the drawback or annealing temperature after quenching. It seems logical to assume that no difficulty would be experienced in living up to a specification for such bars requiring an elastic limit of 70 000 lb. and an ultimate strength of 95 000 lb., or perhaps even 5 000 lb. more for the elastic limit, as the specimen tests gave 83 000 lb. Mr. Norris suggests specifying an elastic limit of from 65 000 to 80 000 lb., and an ultimate strength of from 85 000 to 105 000 lb.; but bridge builders must work to specified minima, hence the writer would like to assume, in writing his specifications for such bars, an elastic limit of 70 000 lb., and an ultimate strength of 95 000 lb., or, if practicable, an elastic limit of 75 000 lb. and an ultimate strength of 100 000 lb.

The excess cost per pound of these finished bars after annealing, as compared with ordinary eye-bars of carbon steel, Mr. Norris indicates would not be more than 3.5 cents.

He anticipates that simple carbon-vanadium-steel eye-bars would have an elastic limit of from 60 000 to 75 000 lb., and an ultimate strength of from 85 000 to 100 000 lb.; but, as it is evident that no actual experiments have been made on finished eye-bars of this kind, it will be well to assume as a specification an elastic limit of 65 000 lb., and an ultimate strength of 90 000 lb. The excess cost per pound of these eye-bars, after annealing, as compared with ordinary eye-bars of carbon steel, the writer deduces from two statements of Mr. Norris to be not more than 1.5 cents.

B.—It is not quite so evident from the discussion that vanadium steel is as suitable for built members of bridges as it is for eye-bars; nevertheless, it seems probable that it would be found to be satisfactory. To determine this would require a series of experiments, consisting mainly of the various shop manipulations of the metal, like those made by the writer some years ago in his tests on nickel steel for bridges. Such a series of experiments could be made at moderate cost.

Mr. Norris states that his Type "A" chrome-vanadium steel will be workable under shop manipulations. From the figures he gives, the writer would deduce that the mills and shops could readily live up to a specification of an elastic limit of 70 000 lb. and an ultimate strength of 95 000 lb., and that the excess cost per pound of the manufactured bridges, as compared with those of carbon steel, should not be greater than 4.0 cents. This would include the cost of annealing (which treatment, it is fair to assume from the general tenor of the discussion, would be obligatory), the extra cost of shopwork, and a small allowance for contingencies.

Mr. Waddell.

From what Mr. Norris anticipates concerning the use of simple carbon-vanadium steel for built members, one may conclude that it would be safe to specify an elastic limit of 60 000 lb., and an ultimate strength of 90 000 lb., and to assume an excess cost per pound of the manufactured bridges, as compared with those of carbon steel, not greater than 2 cents. This last figure is derived thus:

Excess cost of raw material	1.0	cent per lb.
Heat treatment	0.5	" " "
Excess cost of shopwork	0.25	" " "
Contingencies	0.25	" " "
Total	2.0	cents per lb.

C.—It appears likely, from what Mr. Norris remarks, that treated vanadium steel can be manufactured into built members of bridges without losing the great effect of the treatment; but a few practical experiments would determine this beyond the peradventure of a doubt. It is likely that it would prove better to drill the rivet holes than to sub-punch and ream them. This would add only a small amount to the cost per pound of the shopwork.

Mr. Norris does not say whether vanadium steel can be bent cold without injury; hence one may surmise that it cannot. However, this would not militate greatly against its use in bridgework, because in long-span structures (the only kind now under consideration) there should be very little, if any, metal to be bent.

D.—In respect to rivets, Mr. Norris advises for chrome-vanadium steel an elastic limit of from 50 000 to 65 000 lb., and an ultimate strength of from 70 000 to 90 000 lb.; and for simple carbon-vanadium steel an elastic limit of from 40 000 to 55 000 lb., and an ultimate strength of from 65 000 to 85 000 lb. He says "There should be no difficulty in driving rivets of either of these types of steel." True enough; but there might be great difficulty in cutting them out—and, alas, owing to the frailty of human nature, it is impossible to build bridges without having to remove at least a few rivets—and generally a good many of them.

In his experiments on nickel steel for rivets the writer encountered this difficulty, and he was obliged, in consequence, to lower the carbon content (and hence also the elastic limit and the ultimate strength) in his specifications for rivet nickel steel. Nothing but some thorough experiments on vanadium-steel rivets of varying compositions will determine how high a steel it will be safe to use for such rivets.

Concerning rivets for bridges built of high-alloy steels, it is a foregone conclusion that the ratio of the strength of the alloy-steel rivets to that of carbon-steel rivets cannot be as great as the corresponding ratio of strength of plate-and-shape alloy steel to that of

plate-and-shape carbon steel. On this account, in high-alloy steel bridges it will be necessary to use proportionately either more rivets or greater rivet diameters—or both. Mr. Waddell

E.—Mr. Norris has spoken in favor of the use of chromium for vanadium bridge steel, although he indicates a preference for simple vanadium steel. It is possible that the latter is preferable for moderately long spans and the former for very long ones. The economic study based on the preceding deductions from the discussion, which is to follow herein, will determine this point. The quantity of chromium recommended by Mr. Norris varies from 0.6 to 0.9%, in combination with manganese varying from 0.4 to 0.6%, or 0.8 per cent. The writer would be inclined to go a few points, say, 20, higher with the manganese, as his experiments on nickel steel indicated the advantage of such a policy; but, perhaps, the addition of the chromium might necessitate some reduction in the manganese.

F.—For a number of years it was thought by the Engineering Profession in general that vanadium in steel acted only as a scavenger, none of it remaining in the finished product, but all passing off with the slag. However, it seems that such is not the case, but that about 80% of the vanadium which is added to the charge remains in the finished product.

It seems, according to Mr. Norris, that the vanadium is very evenly distributed through the ingot, and that not only is there no danger whatsoever of its segregation, but also that its presence in the molten metal tends to prevent the segregation of other substances—notably carbon. This is most reassuring, and is a strong point in favor of the use of vanadium steel for bridge building.

G.—Mr. Norris does not say much about alloying nickel with vanadium or about combining nickel, chromium, and vanadium. Such combinations are purely a question of economics; and only elaborate investigations can determine what should be the constituents and their proportions to produce the best and most economic alloy. From what Mr. Norris states, one might anticipate that the gain by adding nickel to vanadium-carbon steel or to vanadium-chromium steel would be either very small or non-existent.

H.—Mr. Norris is quite convinced that the addition of titanium to vanadium steel would be useless. Perhaps the explanation for this is that the 20% of vanadium which passes off into the slag acts as a scavenger, thus obviating the necessity for any further purification—which is the sole function of the titanium.

I.—Mr. Norris does not reply to the question as to whether there are any other substances than those herein mentioned, which might profitably be added to vanadium steel. His reason, probably, is that he does not know, never having tried the addition of such elements.

Mr. Waddell. It is only extensive experiments that will furnish an answer to this question.

J.—The specifications for the composition and properties of vanadium-carbon steel and vanadium-chromium steel, suggested by Mr. Norris, are very wide in their range, but they are probably as definite as the present state of the art of manufacturing those alloys will allow.

There is one statement near the beginning of Mr. Norris' discussion to which the author must take exception, namely, "In the case of nickel steel, in order to obtain an elastic limit of 60 000 lb. or more, it is necessary to increase the percentage of carbon to undesirable limits."

The plate-and-shape steel experimented on by the writer in his nickel-steel investigation had an elastic limit slightly in excess of 60 000 lb., and was a perfectly satisfactory metal in every essential particular for bridgework. It is true that its manufacture was harder on the tools than ordinary carbon steel, but that feature simply added slightly to the cost of the shopwork. The metal withstood all the shop manipulations as well as ordinary carbon steel; it was just as reliable in every particular; and there was no danger whatsoever from brittleness.

The economics of Mr. Norris' vanadium-carbon and vanadium-chromium steels, as compared with ordinary carbon steels and with the nickel steels which can be obtained to-day for bridgework at the prices last quoted to the writer by the manufacturers, will now be considered. Using the averages just determined in this résumé, we have for the vanadium-carbon steel an elastic limit of 60 000 lb. and an excess pound price of 2.0 cents as compared with carbon steel; and for the vanadium-chromium steel an elastic limit of 70 000 lb. and an excess pound price of 4.0 cents.

On Figs. 29 and 30 are plotted, for simple-span bridges and for cantilevers, respectively, the weights per linear foot of metal for various spans of carbon steel, vanadium-carbon steel, vanadium-chromium steel, nickel steel for $E = 50\,000$ lb., and nickel steel for $E = 55\,000$ lb.; and on Figs. 31 and 32 are shown, for simple-span bridges and for cantilevers, respectively, the economics of the said five classes of steel considered, as follows:

A.—Carbon steel, $E = 35\,000$ lb.

B.—Nickel steel, $E = 50\,000$ lb., at an excess cost, delivered, of 2 cents per lb.

C.—Nickel steel, $E = 55\,000$ lb., at an excess cost, delivered, of 2.5 cents per lb.

D.—Vanadium-carbon steel, $E = 60\,000$ lb., at an excess cost, delivered, of 2.0 cents per lb.

E.—Vanadium-chromium steel, $E = 70\,000$ lb., at an excess cost, delivered, of 4.0 cents per lb.

Mr. Waddell.

Referring to Fig. 31, it is seen that, for simple-span bridges, under the conditions assumed, vanadium-carbon steel shows, for all span lengths, a small but material advantage over all the other steels; and that the vanadium-chromium steel begins to develop an economy over carbon steel at a span length of about 600 ft., and over the two nickel steels at a span length of about 700 ft.

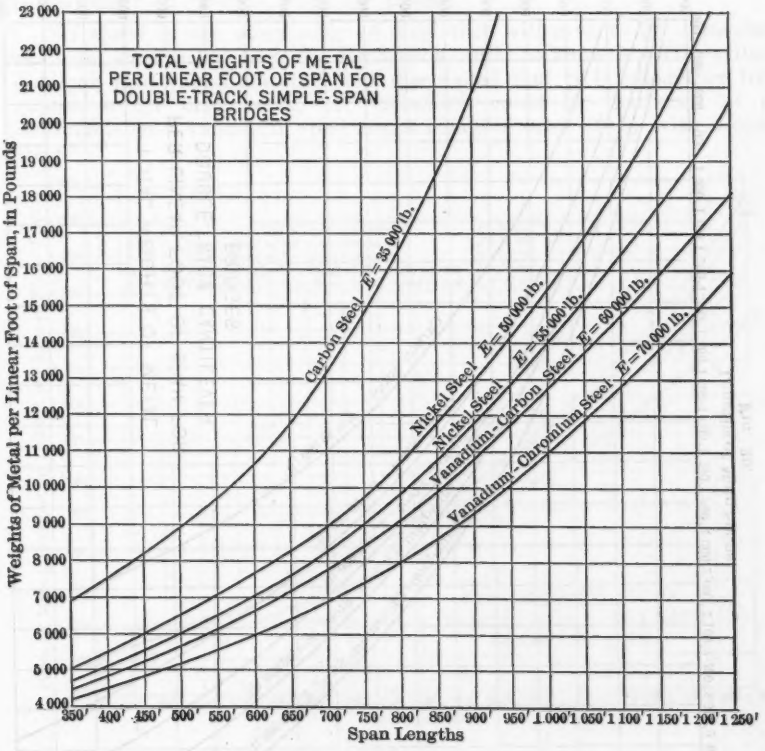

FIG. 29.

Referring to Fig. 32, it is seen that, for cantilever bridges, under the conditions assumed, vanadium-carbon steel shows for all span lengths, as in the case of simple spans, a small but material advantage over all the other steels; and that the vanadium-chromium steel begins to develop an economy over the carbon steel and the nickel steels when the main opening has a length of about 1 600 ft.

Contrary to the writer's anticipation, the lines for vanadium-carbon steel and vanadium-chromium steel, at the excess pound prices assumed, do not cross each other. They would intersect, for cantilever

Mr. Waddell.

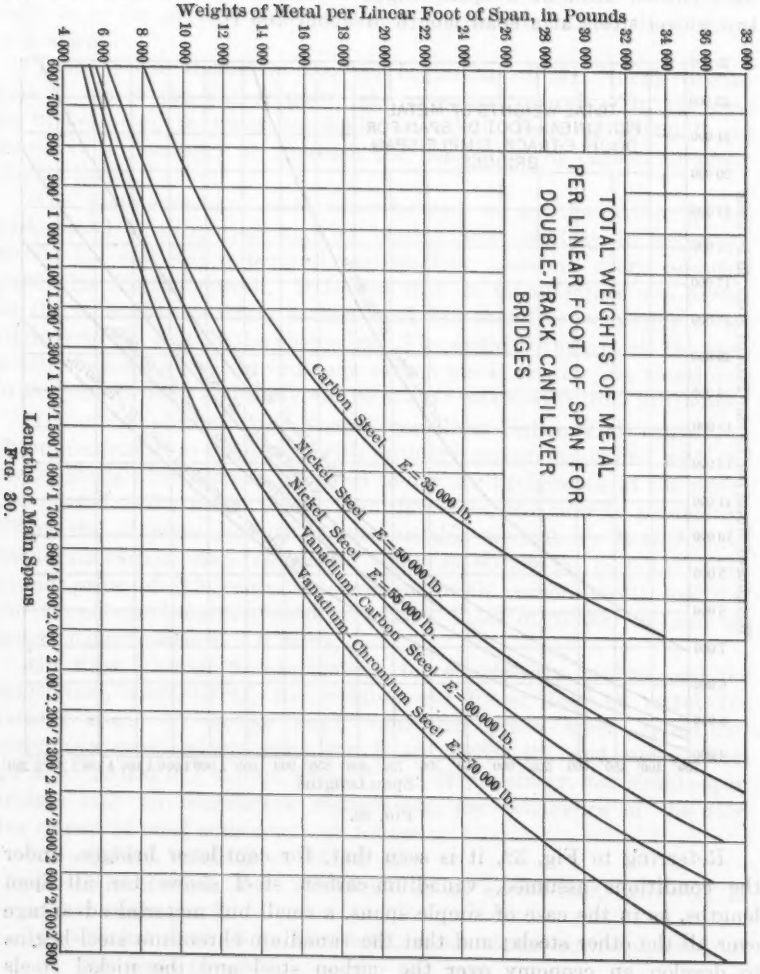

FIG. 30.

bridges, at a main opening of 2 800 ft., which is about the practicable limit for $E = 70\,000$ lb. Mr. Waddell.

Some 8 or 9 years ago certain leading steel manufacturers quoted to the writer an approximate price of 8 cents or more per lb. for vanadium steel bridge superstructures, delivered f. o. b. cars at the shops. It was this which caused him to make the following statement in his paper on "Nickel Steel for Bridges":

"If there is any other alloy of steel that will give as good results as nickel steel at less cost, the Profession ought to know it. The writer did look into vanadium steel, but discovered that it is altogether too expensive for bridgework. If vanadium could be furnished at a reasonable cost, vanadium steel might compete successfully with nickel steel."

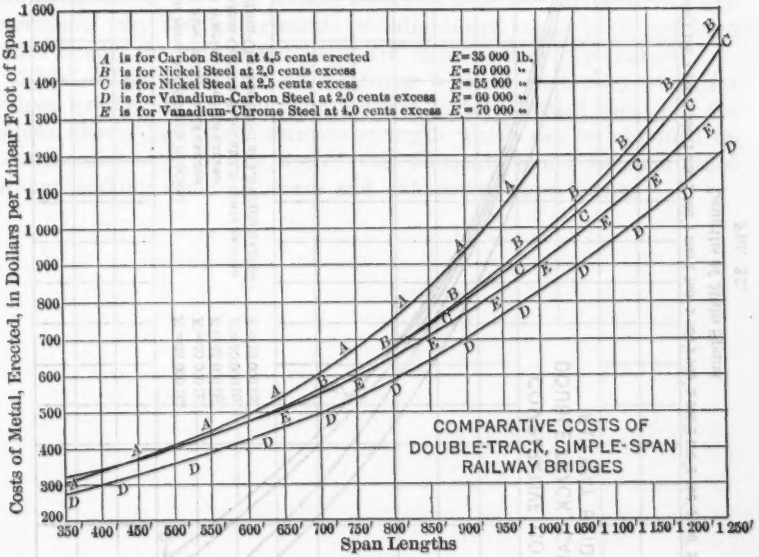

FIG. 31.

Mr. Norris states that "the price of vanadium has been reduced 60% within the past 3 years, and it is now low enough to bring it within consideration for use in steel for eye-bars and other parts of long-span bridges." This statement is corroborated by the preceding economic study; but it must be remembered that the latter is based on somewhat uncertain data. However, the writer aimed to be conservative when assuming the same from the statements in Mr. Norris' discussion; hence, it is easily possible that the vanadium steels, if thoroughly investigated, would show far better economic results than those just determined—in fact, it is not impossible that the ideal

Mr. Waddell.

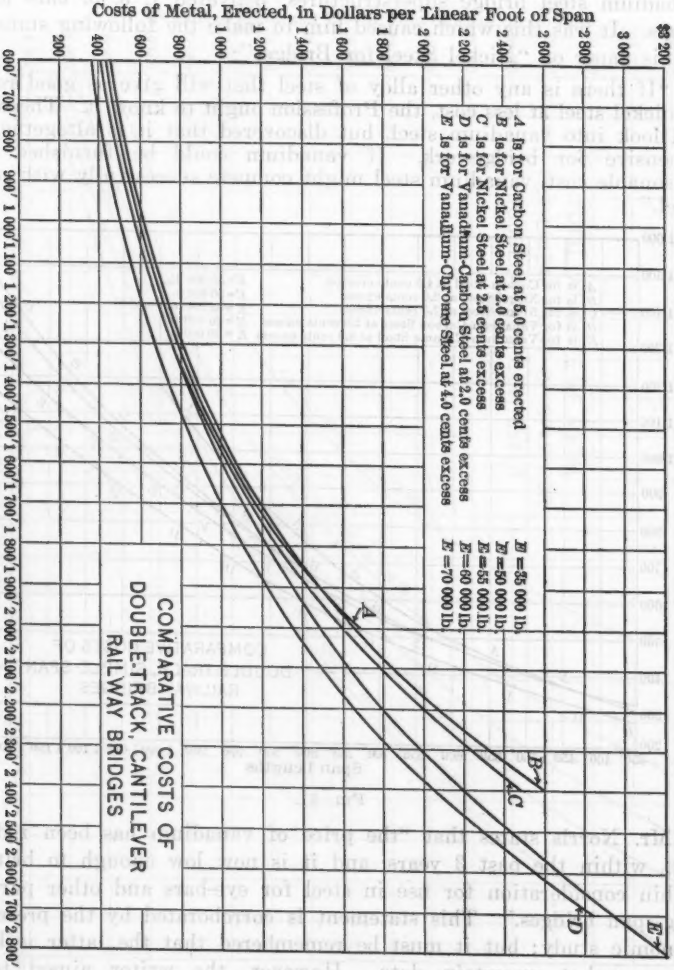

FIG. 32.

workable bridge steel having a minimum elastic limit of 100 000 lb., and of moderate cost, is attainable by the use of vanadium. Mr. Waddell.

Summarizing the findings of the discussion and the résumé, the following conclusions can be drawn:

First.—Titanium as a scavenger of carbon steel promises good and useful results at exceedingly low cost. Although it does not increase greatly the elastic limit or the ultimate strength of the metal, it makes it much more uniform and reliable. On this account it should be used in a few cases on bridgework; and then, if it be found satisfactory, its adoption should be made obligatory by the railroad companies and the other builders of carbon-steel bridges.

Second.—There appear to be great possibilities in the use of aluminum as an alloy for bridge steel; but, as far as the writer can determine, very few experiments in aluminum steels have yet been made; hence, the said possibilities are more or less hypothetical.

Third.—The possibility of obtaining a good, high-alloy steel for bridges by the use of vanadium appears to be a settled fact; but the highest elastic limit and ultimate strength which can be obtained on a commercial basis by the use of that element cannot be determined without making some elaborate and exhaustive experiments.

THE DETERMINATION OF SAFE YIELD OF UNDERGROUND RESERVOIRS OF THE CLOSED-BASIN TYPE.

Discussion.*

By Charles H. Lee, Assoc. M. Am. Soc. C. E.†

Mr. Lee.

Charles H. Lee, Assoc. M. Am. Soc. C. E. (by letter).—Realizing the somewhat local character of his paper, the writer has been highly gratified to find that it has brought forth discussion based on such widely divergent as well as similar experience. He especially appreciates the broad and constructive contributions of Messrs. Smith and Meinzer, whose wide experience with ground-water problems qualifies them to speak with authority.

The writer heartily agrees with Mr. Owen that there is a great need in all sections of the United States for definite scientific knowledge regarding the principles which should govern ground-water development. He would not, however, place such knowledge in the realm of the unattainable, as both Messrs. Owen and Allen in their opening paragraphs seem inclined to do. The Engineering Profession has already made considerable progress in the formulation and application of such principles. In Europe, for instance, where the demand for municipal water supplies has reached the point where the limit of every available source must be known, there has been accumulated such a fund of knowledge derived from investigation and experience that the subject is recognized as a distinct branch of the profession. In the United States the exhaustive investigations of ground-water supply, such as that made on Long Island by the City of New York and the work of the United States Geological Survey, show that

* Continued from September, 1914, *Proceedings*.

† Author's closure.

Mr. Lee.

in America, also, the subject has advanced far beyond the stage of conjecture. It is the writer's opinion that the time is now ripe for the formulation of general principles and methods of investigation and development of ground-water among American engineers, and it was with this in view that his paper was written. It is to be hoped that similar papers will be presented by members of the Society who have had opportunity to study other types of ground-water occurrence, in order that a more complete presentation of the subject in its most recent development may become available to the profession.

The writer was much interested in the statements of both Messrs. Smith and Meinzer that the term "water-tight" as applied to ground-water reservoirs is a relative one, and that, in many arid States, it does not apply at all. Their experience and the writer's more recent observations outside of California are in accord in this matter, and the first conclusion of the paper (page 818*) should be modified accordingly. In all the California basins which have come under the writer's observation, however, the term can be used for all practical purposes. These basins occur either in granite or in tertiary sandstones and shales, and, as the fill is recent, the difficulty encountered by Mr. Smith in defining the basin seldom arises.

Both Messrs. Meinzer and Smith have commented on transpiration losses, and the latter has contributed the first really useful statement of basic principles which the writer has seen. It is to be hoped that further work will be done to confirm the principle of equal relative rates of transpiration, and that quantitative determination be made of the ratio between evaporation and transpiration. In all such experiments care should be taken to measure evaporation under some standard condition, for, as is well known, the results derived from pans in large bodies of water, in wet soil, in dry soil, and in air, differ widely, and in the same environment differ with atmospheric exposure.

In this connection the writer wishes to call attention to the fact that Mr. Smith's conclusion (page 1955†) that the combined loss by evaporation and transpiration from salt-grass sod is twice that from damp soil alone is not justified. The rate of water evaporation from the deep tank in the soil far exceeded that from soil during the winter, for the reason that the soil was kept cold by evaporation and cold air temperature, while the water was free to circulate and received warmth from the deeper soil. Experiments (which the writer carried on but did not publish) indicate that the annual evaporation from saturated base soil is about 93% of that from the water surface in the deep tank. The combined transpiration and soil evaporation for similar conditions was 115 per cent.

* *Proceedings*, Am. Soc. C. E., for April, 1914.

† *Proceedings*, Am. Soc. C. E., for August, 1914.

Mr. Lee.

With these general observations the writer will pass on to detailed comments on the discussion of the paper. Mr. Smith's paragraphs, grouped under the head of "Estimates of Safe Yield" (pages 1956-62*), will be taken up first.

1. The conditions on the slopes of the Catalina and Rincon Mountains, described by Mr. Smith, are not as similar to those of the east slope of the Sierra Nevada as would appear at first glance. Table 3 shows that the lowest elevation of the Sierra slopes is 6 500 ft., the average 7 500 to 8 000 ft., and the maximum elevation 12 000 ft. The similar slopes back of Tucson extend from an elevation of 3 000 to about 6 000 ft. The Sierra slopes do not support a luxuriant desert vegetation nor forest growth, the latter, especially, being spotted and sparse. The precipitation on the Sierra slopes is all in the form of snow, which melts and sinks into the porous mantle before the growing season commences. On the intermediate slopes of the Catalina Mountains, however, the precipitation occurs largely in severe summer storms, from which the run-off is rapid and the percolation is immediately available to vegetation. These differences are all such as to favor greater percolation on the Sierra slope. Furthermore, there are numerous springs at the base of the Sierra slopes, the flow of which, in many cases, can be measured in second-feet instead of cattle drinks. Hence, the writer still believes that the run-off coefficients used are not excessively high.

2. Charlies Butte is a low mound of lava near the margin of a shallow flow which advanced out over the valley-fill. The Butte is not the crest of a bed-rock projection, as Mr. Smith suggests, but is superimposed on the valley-fill. The spring is of the type described by the writer on page 844,† and unquestionably has its source in percolation from the outwashed slope.

3. The writer believes that Mr. Smith is justified in giving a value to transpiration from the luxuriant desert vegetation, the roots of which are within reach of the water-plane. The addition of this quantity would increase the computed ground-water discharge from the basin.

4. Relative to the matter of underflow from the basin past the Alabama Hills, the writer has given this matter considerable thought at various times, and cannot agree with Mr. Smith as to the probability of there being an appreciable loss at this point. For a distance of 6 miles from the "Point of the Hills" to Lone Pine Creek there are no lateral streams breaking through the hills. The whole cross-section was formerly covered by Owens Lake, and any material brought down by Hogback Creek would have been deposited on the lake shore at the "Point of the Hills", or, in case of low lake level, would have been

* *Proceedings*, Am. Soc. C. E., for August, 1914.

† *Proceedings*, Am. Soc. C. E., for April, 1914.

Mr. Lee. carried directly out on the lake bed. There would be no condition favoring or even rendering possible the deposition in the section of any but the finest materials, even on the side adjoining the steep slope of the Alabama Hills. Further, there is the elevated water-plane of the Lone Pine delta opposing such underflow, and the absence of any evaporating area which would naturally result from the back-water effect. Finally, there is the fact that the valley floor of the Independence Basin above the Alabama Hills is an old lake bed beneath which fine sands and clays predominate, that the porous gravels of the outwash slope surround this relatively non-porous core, that ground-water percolating laterally through the gravels meets a barrier at the old lake shore and is compelled to seek an outlet locally by spring flow and evaporation, and that, therefore, the conditions necessary for an active underflow down stream are entirely lacking throughout the whole of the valley floor.

The discussion of probable annual variations in safe yield is not of such great importance for the Independence Basin as in other basins. This is due to two reasons, the immense storage capacity of the saturated gravels and the non-porous core or heart of the valley. The former is relatively very large with respect to any judiciously developed draft, and the latter holds up the water-plane and prevents the escape of water from the basin by underflow. Thus, the fluctuation of the water-plane within a reasonable distance of the old lake shore would not be great, even in periods of extended drought. The effect of variations in ground-water supply in the Independence Basin would appear more as variation in spring flow and evaporation loss than as fluctuation in the water-plane.

Mr. Meinzer's long and intimate experience and scientific study of the problems involved in this paper make him one of the best qualified men in America to discuss it, and his contribution has added greatly to its value. The writer, however, feels that in general his discussion is from the point of view of the pure scientist who strives for absolute accuracy, rather than from that of the applied scientist or engineer whose aim is relative accuracy. There were involved in the solution of this particular problem not only questions of obtaining a proper internal balance in relative accuracy, but also that of giving the problem its proper place in the larger one of determining the safe yield from all sources available for a large municipal water-supply project. The quantity of ground-water available for development from the Independence Basin is about one-fifth of that available from all sources. The writer believes the results obtained, as set forth in this paper, are well within the limits of reasonable accuracy for the purpose desired. Considered in this light, he does not agree with Mr. Meinzer that the assumptions are "subject to large errors."

Mr. Lee.

Considering Mr. Meinzer's discussion in detail, the writer is indebted to him for drawing attention to the erroneous inclusion with ground-water discharge of 18 sec-ft. of irrigation water dissipated by evaporation and transpiration. As has been pointed out by both Messrs. Smith and Meinzer, however, there is an appreciable loss from rank desert vegetation bordering the shallow ground-water area. The inclusion of this with ground-water losses would increase the latter, and, therefore, the corrections in the final result would tend to offset one another.

Mr. Meinzer states that observations covering 1, 2, or 3 years do not give average evaporation conditions, comparing them with precipitation and stream-gauging data in this respect. The writer does not believe that this statement would have been made if evaporation records covering several years had been examined. The range of annual variation in evaporation is usually less than 4%, whereas precipitation and stream flow may have extreme variations of more than 100 per cent.

Mr. Meinzer suggests that, in order to apply the results of the Owens Valley evaporation experiments to other valleys, it would be necessary to have a large number of observation wells and keep them under observation for several years. The writer's experience in other valleys during the past 3 years has been that water-plane fluctuations in evaporation areas follow the same annual periodic law observed, and have about the same range as observed in Owens Valley. Hence the observation of a few judiciously chosen wells at a critical date, preferably late in September, should give dependable results.

The writer agrees heartily with Mr. Meinzer that further investigations of soil evaporation and transpiration under various conditions should be made. In connection with the rate of evaporation from bare alkaline lake beds or "palayas", certain experiments recently carried on under the writer's direction tend to confirm Mr. Meinzer's observations. The evaporation from two pans of water under exactly similar conditions was observed, one pan containing distilled water and the other a sample of highly alkaline lake water. The rate of evaporation from the denser water was less than that from the fresh water, and rapidly decreased to a very small value as the salts began crystallizing out, regardless of the fact that no permanent crust was allowed to form.

SOME PRINCIPLES RELATING TO THE ADMINISTRATION OF STREAMS.

Discussion.*

By John H. Lewis, Assoc. M. Am. Soc. C. E.

John H. Lewis, Assoc. M. Am. Soc. C. E. (by letter).—Engineers are coming to realize the necessity for a more definite administration of streams by the public for the protection of existing and future acquired rights. They know what the law ought to be in order to accomplish the greatest good. Unfortunately, much confusion exists among lawyers as to just what the law really is, for any particular State, or for the Nation. Accordingly, a strong protest is made when any fundamental change is proposed. Little progress can be made in the reform of water laws, therefore, until such time as a large body of thinking citizens can come to some exact agreement as to just what legislation is needed, and then carry on a definite educational campaign to such end. Mr. Johnston's paper dealing with the fundamental principles of good water laws, therefore, should be a welcome addition to engineering literature. Mr. Lewis.

It is pointed out that recognition of the doctrine of public ownership of property in water is the necessary foundation for public control, and that beneficial use should be the basis for establishing and maintaining rights to the use of public waters.

These definite principles are rapidly being accepted as the only logical basis for an administrative code of water laws. The necessity for the adoption of such laws is becoming more apparent each day, as the larger and more expensive projects for the utilization of water are taken up. It would be folly to invest millions of dollars in an undertaking unless firm legal rights to the necessary water can be

* Continued from September, 1914, *Proceedings*.

Mr. Lewis. secured in advance of construction. Further progress in the utilization of our streams demands that definite laws be enacted.

The proper jurisdiction for the enforcement of such laws, however, is a matter of some uncertainty. Any discussion of fundamental principles, it seems to the writer, would be incomplete without some mention as to whether such laws should be administered by the County, the State, or the Nation, or perhaps by the drainage basin, irrespective of State lines. If we recognize the "public ownership of streams", then which of these political divisions shall act for the public in the administration of this public property?

Agreement as to this point seems to be fundamental. In the days of small projects and abundant water, county control seemed adequate. Later, State control was found to be necessary. With the taking up of vast irrigation, drainage, water-power, flood-control, and navigation projects, involving the expenditure of millions of dollars and the building of structures in two or more States, it would seem necessary, in such cases, that the water laws be administered by some authority superior to that of the individual State.

At the outset, when the total investment was small, little attention was paid to the question of legal title to water; nor was much consideration given to problems of administration. If subsequent appropriators caused injury, the wrongful diversion was restrained by injunction proceedings in the Courts. The cost of litigation to preserve prior rights became in time so excessive as to compel early appropriators to insist on the adoption of modern administrative codes for their protection. These laws proved a boon to capital, as definite grants could be secured which would ripen into vested rights when the water was put to use.

Litigation between States over interstate waters is increasing. Eventually, diversions in some States must be enjoined for the protection of water users in lower States. The loss of time and money in protecting States' rights on interstate streams must eventually reach appalling proportions. Capital will hestitate to invest for fear the new diversion when made will be enjoined. The same difficulties which have been encountered between appropriators within a State will be encountered between appropriators in different States. State laws, however perfect, can give little relief. Stagnation in development and the great loss in time and money resulting from such an archaic system of "government by injunction" will compel the adoption of some Federal administrative code of water laws in the future.

The administration of streams is a public necessity. Both State and nation have been derelict in their duty in this regard. Public rights have been shamefully trespassed upon in many cases for want of an administrative department with power to protect the public

interest. Beneficial use is the proper basis for such administrative laws, whether State or National. Mr. Lewis.

The unwise use of public property through lack of a definite administrative water policy for the greatest good to the greatest number occasionally results in great waste. This point may be illustrated by Snake River between Lewiston, Idaho, and Huntington, Ore., where the granting of a railway right of way may defeat the ultimate development of about 800 000 h.p. and the furnishing of water transportation to an empire greater than the combined areas of New York, New Hampshire, and Vermont.

Through lack of a public water department having full power to protect the public interests, we may wake up a few years hence and find that our public land department has granted land rights which will defeat public water rights of very great importance to the proper development of this region.

FIG. 1.

Between Lewiston and Huntington (Fig. 1) there is a fall of 1 300 ft. in Snake River, in a distance of 184 miles. The stream forms the boundary between Oregon and Idaho. At certain seasons it is navigable with great difficulty to Pittsburg Landing, 80 miles above Lewiston. This portion of the stream is doubtless under Federal control. Above this point, it is clearly non-navigable under present conditions, and is probably under the jurisdiction of the States with respect to water appropriations. One bank of this upper portion of the stream is in a National Forest, and the other bank for many miles is withdrawn from entry by the United States as being of great value for power purposes.

The river flows in a deep, rock-walled canyon, and for much of the distance is only from 300 to 400 ft. wide at the water surface. No foundation tests have been made, but conditions seem favorable for the construction of high dams and the ultimate development of about 800 000 h.p. Below the mouth of Salmon River, its low-water flow is approximately 10 000 sec-ft., and above that point 6 000 sec-ft.

On the profile, Fig. 2, there is sketched an ideal system of water-power dams arranged so as not to conflict with a 550-ft. tunnel project on Salmon River. This, with a 220-ft. dam and a 7- or 8-mile

Mr. Lewis.

tunnel, would develop 200 000 h.p., with the 4 000 sec-ft. of water available at low stage.

The lower dam, 175 ft. in height, would make 27 miles of slack water for navigation purposes to the foot of the next dam above. Ultimately, as the market for power increases, this stream, with small additional expense, could be opened to cheap barge transportation incidental to such water-power development. What this would mean to the 43 700 000 acres comprising the great Snake River Basin in Idaho and Oregon, is inconceivable. The United States Census shows 1 611 000 acres to have been irrigated in this district during 1909, and 3 907 000 acres are embraced in projects under way. The storage of water in Idaho for present use, together with diversions from the regular flow, has already injured to some extent diversion and pumping rights in Oregon. How the unrestrained use of water by Idaho in the future will affect Oregon cannot be predicted with the data at hand.

A water-power plant is now being constructed, presumably under State authority, by tunneling across a bend in the river just above Homestead, in Oregon. Will this plant be compelled to submit to Federal regulations at some future time, when the river is actually made navigable, or is declared so? How can Oregon protect its water supply against subsequent diversions in Idaho and Wyoming? Irrigation may be the highest use for water in the valley above, yet it is clear that water-power with incidental navigation is its only use in the canyon below. These are some of the uncertainties arising from the interstate character of the stream.

Although much of this power is supposed to be under the joint control of Oregon and Idaho, for all practical purposes it can be destroyed by the Federal departments controlling the public lands in this canyon, by the granting of a railroad right of way with the grade close to the water surface. Such a road has already been constructed from Huntington to Homestead, 58 miles, and right of way for the remainder of the distance has been granted. The construction of this road would add greatly to the cost of, if it did not entirely defeat, such a plan of water development, if found feasible, in the future. Snake River Valley now has transcontinental railway transportation, and the building of this cut-off on water grade would make but little, if any, difference in rates, compared with water rates. Whether it is feasible to locate such a proposed railroad several hundred feet above the water surface, so as not to conflict with the proposed plan of water-power development, can only be ascertained from a careful survey.

The rapidity with which the electric furnace is developing and opening up new possibilities for the utilization of vast quantities of electrical power, makes this project somewhat hopeful of materializing, from the standpoint of finding a market for the power. It is one which seems

Mr. Lewis.

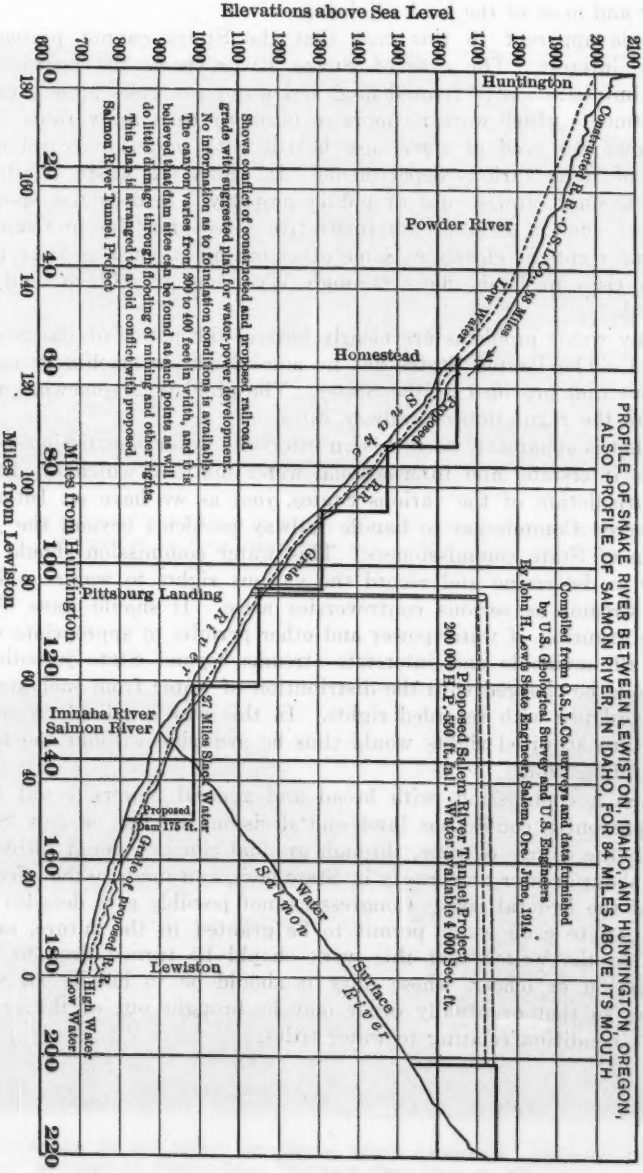

Fig. 2.

Mr. Lewis.

to be worthy of careful consideration by the public which owns the water and most of the land adjoining.

It is apparent in this case that the States cannot protect the public interest. The case of Snake River shows the confusion in the administration of related land and water resources among various departments which work no more in harmony than the various States. It shows the need of some new boards with power to correlate the work of these various departments. It shows the waste which may come through unwise use of public property. It does not show the need of such a Federal administrative board for the protection of existing rights as clearly as some other examples, such as Bear River, which rises in Utah, flows through Wyoming and Idaho, and ends in Utah.

Many water problems are clearly beyond the power of the State to control. The United States has no administrative machinery to supplement that provided by the States. The problem is somewhat analogous to the regulation of railway rates.

What is apparently needed is an interstate water commission to handle all interstate, and international water matters, which are beyond the jurisdiction of the various States, just as we have an Interstate Commerce Commission to handle railway problems beyond the jurisdiction of State commissioners. This water commission should have power to determine and record the various rights to water on interstate streams as serious controversies arise. It should have charge of the granting of water-power and other permits to appropriate water from all navigable and interstate streams beyond State jurisdiction. It should be charged with the distribution of water from such streams in accordance with recorded rights. In this way a reliable record of all future acquired rights would thus be available without the necessity of litigation.

Such a commission, with broad and general powers, could study the apparently conflicting laws and decisions of the various States and, in the course of time, through gradual changes, could ultimately bring about greater uniformity in State laws, and increase the effectiveness of the Federal laws. Congress cannot possibly give detailed consideration to each water permit to be granted in the future, and it seems to the writer that this work should be turned over to some commission or officer, whose duty it should be to handle all water matters so that eventually order may be brought out of the present chaotic condition relating to water titles.

DISCUSSION ON VALUATION FOR THE PURPOSE OF RATE-MAKING.*

By J. P. Hallihan, M. Am. Soc. C. E.

Mr. Hallihan.

J. P. Hallihan, M. Am. Soc. C. E. (by letter).—Throughout the discussion on the report of the Committee, there does not appear to be any mention of the shrinkage in the value of railroad securities that is now taking place and the apparent necessity of devising some method of financing for the future that will tend to stabilize those values; a method that will not curtail enterprise, while reducing to the minimum the inflation of securities. It may be argued that the discussion of methods of financing lies outside the province of this Society, but the writer believes that this view will be taken by few engineers who have witnessed the evil effects, both on the property and on the security values, that follow unrestrained manipulation of securities and capitalization of surplus earnings, or the further and perhaps more disastrous results in retarded development of resources that will follow a regulation of roads and security issues, that eliminates the speculative profit without increasing the safety of the investment.

Before offering any suggestion as to changes, it is well to consider the present system of financing new roads, a system which has been applied to all or nearly all of our present railroads. Theoretically, the securities of a railroad should produce cash in amount equal to the face value less the usual bankers' and brokers' commissions, and this situation may at times be approached in the case of extensions by roads long established in profitable territory, maintained to a high standard, and with surplus earnings sufficient to guarantee interest on bonds and to assure the payment of dividends on stock.

* Continued from August, 1914, *Proceedings*.

Mr. Halliihan.

In the case of a new road these guaranties cannot be furnished. In support of the securities there exist only partly developed resources —potentialities—which, combined with personal effort and capital, may be moulded into a state of productiveness sufficient to support a railroad.

Where is the required capital to be obtained? Those having the most faith in the enterprise and whose property will be most benefited by it, have already done their best to make it possible by carrying on the initial development of resources and, in this effort have expended all their capital. Those living in more prosperous communities, supplied with transportation, and still sensible of the benefits to be derived from the use of transportation facilities, are also mindful of the hazards attending the early days of that form of investment, and confine their purchase of securities to those of going concerns. The enterprise, therefore, is forced into the general money market with a security known as a construction bond carrying a low rate of interest and having behind it only a charter, some surveys and estimates, and the good-will and confidence in themselves—of their ability to fill the measure of their promises—of the communities desiring the facility.

In competition with high-class securities, supported by visible assets, the construction bond is hopelessly handicapped, and the enterprise is forced to seek the help of some financial entity strong enough to advance the necessary capital against the bonds and to assume as well the responsibility of creating the assets on which the bonds are to rest.

What is the value of this service, which in effect is the vitalization of the enterprise?

Naturally, any banking house furnishing the capital for a new project must be put into a position to control the expenditures, as it assumes a certain responsibility toward the individual purchaser of the securities. This requires actual stock control, so that at the inception of the enterprise at least 51% of the stock must be issued to the bankers, or trusteed in some manner so that they obtain voting control.

It has been the practice in the United States to deliver the bonds to the bankers at a discount sufficiently below the probable selling price to the public to allow for bankers' and brokers' commissions, and to turn over to them as well the entire issue of capital stock less such portion as promoters may be permitted to retain for their services in bringing the project up to the point where it will stand financial analysis.

The banker does not retain all this stock, for, in disposing of the bonds to his clientele, he, in turn, is forced to offer stock as a bonus in order to attract investors from the more conservative channels of

Mr. Halliban.

investment, for even at a liberal discount and supported by the endorsement of a reliable banking house, a construction bond is always considered a speculation and the purchaser is entitled to a share in the speculative profits of the enterprise, in addition to the interest earned on the bonds.

Inasmuch as no actual money has been paid by any one receiving this stock, it appears that something has been given for nothing, but an analysis of the comparative values shows that, if value is measured by the market quotation and demand, neither stock nor bonds have more than a nominal value in the market, nor can they have until the enterprise is carried through to a successful termination. In the meantime, the bankers, willingly or otherwise, must share with the promoters the responsibility for the project, and must be prepared to support it through the vicissitudes of the construction period and of the early years of operation, or the development period.

The stock, therefore, must be considered as a promise to pay at some future date for the brains, personal effort, and credit (as fitly stated by Gardner S. Williams,* M. Am. Soc. C. E.) utilized in creating and administering the property. Both in time and amount, this payment is directly dependent on the success attending the use of the faculties mentioned. If unsuccessful, the consideration is of no value. If successful, those who take the risk are entitled to a reasonable proportion of the fruits of that success.

When the enterprise emerges on a self-sustaining basis and earns a surplus, over fixed charges, sufficient to enable a dividend to be paid on the stock, a market is created and the stock now becomes a speculative investment, gradually passing from the original financiers into the hands of the general public.

Up to this point, useful work has been performed by the promoters and bankers, new wealth has been created, and the risk assumed by the capital has been remunerated to the satisfaction of every one concerned, including the actual users of the service. Thus far, the public, regarded as the user, has suffered no injury. It did not participate in the original investment, assumed none of the risk, and helped only passively to create the value. A high price has been demanded for the capital used, but the payment of this price was justified by the narrowness of the market for the securities offered and the pressing need of the facility. At a less price, or without the attraction of a speculative profit, the capital could not have been obtained unless the risk was reduced by increasing the local equity, or by some form of interest guaranty, both usually impracticable.

Theoretically, the public, having now purchased a majority of the stock, is the owner of the road and is responsible for its administration and for the disposition of its earnings. Actually, the road

* *Proceedings*, Am. Soc. C. E., May, 1914, p. 1407.

Mr. Hallihan.

is effectively held by the original financial group, now very greatly in the minority as to stock ownership, having taken their speculative profit; but a minority highly organized, which has named the directors, installed the management, and decides the financial policy. The buying and selling of stock on the exchange rarely disturbs this control, but if it is disturbed, it merely passes to another similarly organized minority.

Certain abuses of this power, in the way of questionable financial deals conducted by inside syndicates, distribution of unearned dividends to assist the manipulation of securities, and a general exploitation of properties with disregard of the interests of the stockholders and the users, have been followed by regulatory acts, which, at times, may have merited the criticism of being too drastic, since it has been impossible to differentiate between well managed and badly managed properties.

The work done by the Interstate Commerce Commission, however, has been along constructive lines. It has benefited the position of the user of transportation by relieving him of unfair discrimination and kindred evils; it has constituted the Commission the balance of power between the large and the small stockholder, or between the organized minority and the unorganized majority, and in this respect has materially improved the security market, because it has created in the mind of the small investor a feeling that his investment is being looked after by a disinterested arbiter, and has thereby widened the market for railroad securities—a distinct benefit to the bankers. The valuation of public utilities (though there may be some difference of opinion as to such valuation being the proper method for determining rates) is nevertheless bound to effect a wholesome change in the disposition of the earnings of railway properties. All this tends toward establishing security of investment, and is, therefore, constructive work.

The restrictions surrounding bond and stock issues of new transportation projects, however, have practically eliminated the speculative profit that was offered to capital when our present railroad systems were built, with the result that capital hitherto utilized in developing transportation facilities has been directed to other and more attractive forms of investment or has found use abroad.

It is the writer's belief that this is a condition of sufficient economic importance to warrant the consideration of the Society in connection with the valuation of public utilities, as there is still a large area of our country unprovided with transportation facilities and rapidly developing to a point where the inhabitants will have a right to demand that such facilities be supplied. Before money can be obtained for such purposes, the differences of opinion now existing between the various regulatory bodies and the bankers must be harmonized

Mr. Hallihan.

and a financial basis arranged, which will at once protect the user of transportation and provide adequate return for the risk assumed by the financier and investor at the various stages of the enterprise. The questions to be considered appear to the writer to be as follows:

1st.—What, if any, investigation should be made by the Interstate Commerce Commission of the necessity for a transportation facility prior to issuance of a charter by the State?

2d.—What limitation per mile should be placed on the bond issue for single-track roads in:

a. Territory yielding a light traffic?
b. Territory yielding a heavy traffic?

3d.—What discount should be allowed on the bonds?

4th.—What proportion should the share capital bear to the authorized bond issue?

5th.—What proportion of the share capital should be allotted to the bankers and promoters in payment for their services and credit—to insure control and as speculative profit? At what discount should the remainder be offered to the public?

6th.—If speculative profit is not allowed, should any guaranty be given by the Government in any form to reduce the risk to an investment basis, and what reversionary rights should the Government receive in exchange?

7th.—What provision should be made for amortization of bonds?

In asking this latter question, the writer suggests that a difference of opinion may reasonably exist as to the definition of the word "depreciation." If depreciation is taken to mean the difference between the present value of an article in use and the new value of the same article, it is apparent that a fund set aside for the purpose of maintaining that article in a condition of 100% efficiency cannot be used to provide for replacing it with a tool of double the efficiency and costing twice as much. The necessity of replacing an old article with a superior one is due to the fact that the old article has become obsolete. A 60-lb. rail, on untreated ties, on an unballasted roadbed, is not replaced with a 60-lb. rail, but with a 90-lb. rail, on treated ties, on a well-ballasted roadbed. The mere maintenance, therefore, of the original rail in a state permitting it to perform the service which may be performed by a 60-lb. rail may call on the earnings for just the amount necessary to maintain that condition and to replace it when worn out, and no more. To supply the additional and further amount that is required to bring the transportation tool up to a present-day efficiency, new capital must be provided, whether out of earnings or otherwise.

When the replacement is made a value will be wiped out, which is the difference between the scrap value of the old rail and its

Mr. Hallihan.

efficiency value when laid on the roadbed and performing its work. This value has been used in the performance of its work, and at the time when the rail is taken up, the same value should have disappeared from the original loan. That is, the bonds should have been reduced in amount covering this loss; or, in other words, the borrowing capacity of the road must be kept up to provide the extra capital required for obsolescence.

The discussion apparently indicates that both these quantities are assumed to be included in the one account—depreciation—but it would seem that for the sake of clearness in accounting, it would be desirable to create a separate fund for amortization of bonds.

8th.—What is a fair return to the stockholder?

9th.—In the case of roads operating under competitive rates, but still earning a surplus over a fair return, should the surplus be permitted to accumulate as a surplus for ultimate division among the stockholders as extra dividends, or be applied to an interest reserve fund for extensions and betterments?

The writer suggests discussion of these questions in the belief that the Society, from the experience and training of its members, is well qualified to deliver an impartial opinion and to formulate standards of practice that may serve to establish railroad investments on a more attractive as well as on a sounder financial basis.

DISCUSSION OF CONDITIONS OF EMPLOYMENT OF, AND COMPENSATION OF, CIVIL ENGINEERS.*

By Jules E. Hanique, Assoc. M. Am. Soc. C. E.

Mr. Hanique.

Jules E. Hanique, Assoc. M. Am. Soc. C. E. (by letter).—This problem is of vital importance, as its solution will affect the majority of engineers of all classes. The revised and enlarged tables which the Committee is now preparing should yield very important and needed information.

The writer has read all the discussions to date, and wishes to concur in the opinion expressed by Messrs. Phelps, McCullough and Fuller, as to the necessity for a "clearing bureau," maintained by the Society, for the benefit of all the members.

Neglecting the higher positions, held by those whom Mr. Fuller and Mr. Henoch call the successful engineers living in an environment of "big things", the writer would like to make a few remarks on the condition of the "submerged ten", and show some reasons for their "unethical conduct in seeking work at a wage below the standard."

It is important to make a difference between an engineering position and a job of engineering; inasmuch as a "position" means work at a fixed salary, usually on the staff, and the incumbent enjoys many advantages. After working hours he is free to associate with whom he pleases; he can read up on any pet subject; he has access usually to some good library; but the important point is that his position, being of a permanent nature, he can arrange his budget of expenses and regulate his income almost to a certainty for a long period of time. He can invest his savings to advantage, and, being

* Continued from May, 1914, *Proceedings*.

Mr. Hanique.

on the ground, can also watch them more closely. His leisure can be arranged so as to give him the maximum benefit, through his reading, studies, and principally through the careful selection of his associates, which can be made to yield large returns.

Men of the other class, they who follow "job engineering," have an entirely different "row to hoe." The experience of many such has been summed up by Mr. Fuller. Twenty-four hours' notice is not unusual, and, in some cases known to the writer, less time has been given. Is it any wonder that the men thus dismissed are badly handicapped? If the man has a family, it is still worse; he must move at once to some large center from which to start a new campaign; he must go around again and pick up his old acquaintances; he must, patiently and cheerfully, go from one man to another, up and down stairs and elevators, in and out of offices, past clerks and stenographers, and brave the withering looks of office boys and prospective employers; but he must remain neat, presentable, and, above all else, cheerful.

He knows that his savings are running low, and that prospects are not very good, but still he must keep on looking. The situation becomes critical. Under the circumstances, what is he to do? Work at anything, until something turns up; and who is there to blame him? It may be unethical, but it is eminently necessary and certainly practical.

It is very well in times of plenty to talk of standard wages, but it is to be borne in mind that, when work is plentiful, no engineer, nor any one else for that matter, will work for less than the market value of his class of work.

The salaries for engineers is one of the mysteries of the age; some attempt has been made at fixing salaries for different classes of work, but on what basis? A muck foreman's wage is determined by the amount of work he can get out of his gang; a general foreman will receive a salary greater than that of the engineer on the job; and the engineer is supposed to know the work of all the foremen, in addition to his own. Why should this be? What becomes of the "prep." school work? What of the four years of collegiate work? What is the incentive to the young man in the face of these conditions?

The Society, in so far as the welfare of its members is concerned, fails just when it is most needed, as a not too liberal interpretation of Section 3, Article I, of the Constitution will show.

The Society has many local branches scattered about the United States, and it seems to the writer that through them it would be feasible and inexpensive to maintain a register of positions open in the particular district in which such local branch is situated. All unemployed members could have access to this register on payment of a fee large enough to reimburse the local association for any expenses it may have incurred.

Mr. Hanique.

The writer assumes that members of the Society in good standing would be given the preference, because the fact of their being a member should be *prima facie* evidence of ability, or at least of experience. If many are incompetent, as has been suggested, the fault lies in the admission requirements, and these should be changed.

The writer sees nothing in these suggestions tending to lower the dignity of the Society or of the Profession, and earnestly commends the foregoing to the attention of all members, believing that the subject is too big and too vital to be classed as mere academic discussion and tabled.

The writer assumes that members of the Society in good standing would be given the preference, because the fact of their being a member should be prima facie evidence of ability, or at least of experience. If many are incompetent, as has been suggested, the fault lies in the admission requirements, and these should be changed.

The writer sees nothing in these suggestions tending to lower the dignity of the Society or of the Profession, and certainly commends the foresight to the attention of all members, believing that the subject is too big and too vital to be classed as mere academic discussion and tabled.

THE CONSTANT-ANGLE ARCH DAM.

Discussion.*

By Messrs. D. C. Henny and Edward Wegmann.

Mr. Henny.

D. C. Henny, M. Am. Soc. C. E. (by letter).—The economical design of arch dams in canyons of considerable width at the bottom and with practically vertical sides, calls for a constant angle and constant radius. The author deserves full credit for pointing out that in canyons which are more distinctly V-shaped the design requires a variable radius and as far as possible a constant angle in order to obtain maximum economy.

It does not need much mathematical analysis to be convinced of the general correctness of his reasoning, and the writer is in part responsible for the adoption of a similar design for a dam of this type, now under construction.†

With the more detailed reasoning in the author's analysis of interior stresses throughout the body of masonry, however, the writer cannot fully agree, largely because he does not believe that the facts correspond entirely with the assumption on which the analysis is based.

It has been assumed by the author, as is customary in studies of this kind, that the weight of the dam is transferred vertically downward to the foundation, and that the water pressures against the structure are transferred horizontally to the abutments. A division of the loading is thus arrived at between the vertical cantilever and the horizontal arch, and Poisson's ratio is further applied in an attempt to approximate more closely actual stresses and deformations.

* This discussion (of the paper by Lars R. Jorgensen, M. Am. Soc. C. E., published in May, 1914, *Proceedings*, and presented at the meeting of September 16th, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

† Clear Creek Dam, Washington.

Mr. Henny.

This method of reasoning may be logical in the case of a dam almost as long at the bottom as at the top. The principal subject of the paper, however, is believed to refer especially to dams with V-shaped rather than U-shaped longitudinal sections, and to such dams this reasoning is not believed to be logically applicable.

In the matter of the distribution of foundation pressures due to gravitation alone, a difficult problem is presented in which the shape of the canyon and the method of construction become important factors.

If a dam is built as a monolith and brought up horizontally, with the layers well connected or interlocked by large rocks, and if the sides of the canyon are steep, the dam becomes to a large extent a wedge, and the load will be partly transferred from the middle to the sides of the canyon through combined arch and beam effect. Thus, the loading at the bottom of the canyon will become greatly reduced.

If, on the other hand, the dam is built with vertical contraction joints, the horizontal load transference will become reduced, although friction along such joints, if under heavy pressure through lateral expansion due to vertical loading and through horizontal water loading, will still leave considerable beam and arch effect.

If the dam is built up in vertical slices with large vertical joints between, and these joints are finally filled, under the most favorable conditions of temperature, not only will lateral pressures from vertical loading be almost completely nullified, but entirely different conditions as to initial stresses will exist.

The effect of the shape of the canyon and the difference in methods of construction will be equally important as to transference of horizontal water loading.

If Fig. 18 represents the developed longitudinal section of an arch dam, it is evident that in a dam of that type, the shortest distance of a point *a*, in the mid-vertical cross-section, to the abutment does not lie in a horizontal, but in an inclined direction, approximately normal to the slope of the canyon. A down-stream movement of the point *a*, such as may result from water pressure, therefore, will produce relatively more deformation and compression in the direction *ab*, than in the direction *ac*.

In transferring water loading from the middle to the ends of a dam, the stresses or lines of pressure, therefore, will be deflected through weight and possibly tension into curved lines, and thereby follow shorter than horizontal lines to points of support, as indicated by the dotted lines on Fig. 19.

If *ede* represents such lines of pressures, then the arch which mainly transfers the load, will have its crown at elevation *d* and its springing lines at the lower elevation, *ee*, and if developed will ap-

proximate an elliptical shape, with largest radius of curvature and with least thickness at the crown. Mr. Henny.

If these pressure lines are representative of stress distribution, it is evident that there will be an increase in intensity of pressure near the top of the middle section and a corresponding decrease at the bottom.

If the dam is not built as a monolith but with contraction joints, there will be a lesser tendency to deflection from the horizontal; but, through friction in connection with initial and loading stresses, much of this tendency will remain, and it is quite probable that even then the pressures in the lower part of the dam, both up stream and down stream, may be profoundly affected by load transference.

In any study of division of load between arch and cantilever, moreover, it should be remembered that any inclined plane from the canyon walls to the top of the dam may develop a section which, considered as a cantilever, may, because it is shorter, be stronger and, therefore, have greater effect in opposing true arch action than the vertical cantilever on which the author's reasoning is based.

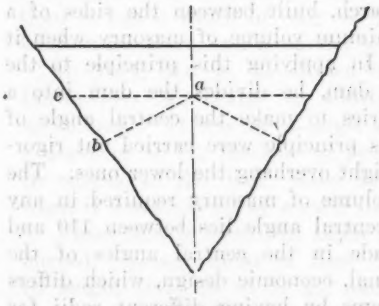

FIG. 18.

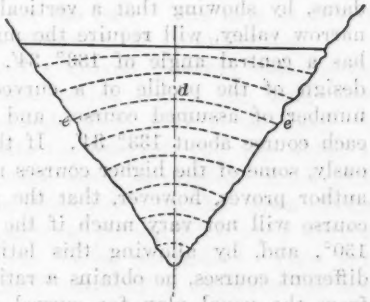

FIG. 19.

To summarize, the writer holds that if an analysis of interior stresses in a dam placed in a V-shaped canyon is to yield satisfactory results, it is essential that the section of the canyon along the center line of the dam should be made a factor in the problem.

This discussion is submitted with a full appreciation of the principal point brought out in the author's valuable paper.

EDWARD WEGMANN, M. AM. SOC. C. E.—The speaker will review briefly the opinions about arch action in curved dams, that have been advanced by different authorities. M. Delocre, a French engineer, investigated this subject in 1866, and reached the conclusion that a curved dam would act as a dam, providing its thickness at the base did not exceed one-third the radius of its up-stream face.* Another Mr. Wegmann.

* "Mémoire sur la forme du profil à adopter pour les grands barrages en maçonnerie des reservoires," par M. Delocre. *Annales des Ponts et Chaussées*, 1866, 2e Semester, p. 212.

Mr. Wegmann.

French engineer, M. Pelletreau, placed the limit of the thickness of the base, of a dam which will permit arch action, at one-half the radius of the up-stream face.* Professor Rankine, M. Krantz, and some other eminent engineers thought there were so many uncertainties involved in the assumptions made in the mathematics of arch action in dams, that they recommended that a masonry dam should always be designed so as to be able to resist, by its weight alone, the pressure of the water, and that, in the case of a narrow valley, the plan of the dam should be curved, as an additional safeguard, to utilize arch action.

During the preparation of the plans for the Lake Cheesman Dam, in Colorado, Silas H. Woodard, M. Am. Soc. C. E., made a very interesting mathematical investigation of arch action in curved dams.† This subject was carefully studied, also, taking into account stresses caused by changes of temperature, by George M. Wisner and Edgar T. Wheeler, Members, Am. Soc. C. E., in connection with the plans for the Pathfinder Dam.‡

Mr. Jorgensen has taken a step in advance in the study of curved dams, by showing that a vertical arch, built between the sides of a narrow valley, will require the minimum volume of masonry when it has a central angle of 133° 34′. In applying this principle to the design of the profile of a curved dam, he divides the dam into a number of assumed courses, and tries to make the central angle of each course about 133° 34′. If this principle were carried out rigorously, some of the higher courses might overhang the lower ones. The author proves, however, that the volume of masonry required in any course will not vary much if the central angle lies between 110 and 150°, and, by allowing this latitude in the central angles of the different courses, he obtains a rational, economic design, which differs from the usual plan for curved dams by having different radii for the up-stream face at different levels. The method is novel, and is theoretically correct.

The author states, on page 1287,§ that:

"Arch stress is distributed nearly evenly over the whole section, whereas the stress due to gravity action is very poorly distributed, being a maximum along the down-stream face, and diminishing to approximately zero at the up-stream face."

The speaker cannot fully accept this statement. Owing to the elasticity of the masonry, a curved dam will yield slightly when subjected to water pressure. This motion will be greatest at the center of

Mr. Wegmann.

the valley and practically zero at the sides which form the abutments of the arch. It follows, therefore, that although we can calculate the compression in the arch by the simple, well-known formula given on page 1288,* this stress may not be uniformly distributed, as the slight yielding of the arch will cause the line of pressure to shift nearer to the up-stream face. In the present state of knowledge, it would be difficult to say whether the distribution of stress in the dam, considered as an arch, varies any less than that which is usually assumed to be caused in the masonry by the action of gravity.

Turning from theory to practical examples, we find that the plans of the old Spanish masonry dams, which were built more than 300 years ago, are curved or polygonal in plan, being convex up stream. About 1843, before any correct theory had been advanced for the design of masonry dams, M. Zola built a curved masonry dam to form a reservoir for the water supply of the City of Aix, in the southern part of France. This dam, known as the Zola Dam, is so thin that it cannot resist the water pressure by its weight. Its stability is solely due to arch action. For a height of 120 ft. above the foundation, it has a width of only 42 ft. at the base. The dam is 205 ft. long on the crest, and is curved to a radius of 158 ft. at the top.

In 1884, Mr. F. E. Brown built a curved masonry dam in the Bernardino Mountains in California, which equals the Zola Dam in boldness. It was 64 ft. high and only 20 ft. wide at the base. At a depth of 48 ft., the line of pressure for reservoir full was about 13 ft. outside of the dam. This structure stood successfully until 1910, when it was replaced by a safer dam, about 200 ft. farther down stream.

From 1896 to 1906, Mr. Leslie Augustus Burton Wade built thirteen curved, concrete dams in New South Wales, Australia.† They vary in height from 25 to 87 ft., and their masonry is subjected by arch action to maximum pressures of from 20 to 25 tons per sq. ft. The highest of these dams has a width of base of 24 ft. for a height of 87 ft.

At the end of his paper the author mentions three dams which have been built successfully on the constant-angle arch principle. The profiles of these structures are rather peculiar, but this is due to the author's attempt to get a better distribution of stresses and a smaller volume of masonry than are to be found in the ordinary curved dam.

SUBAQUEOUS HIGHWAY TUNNELS.

Discussion.*

By J. V. Davies, M. Am. Soc. C. E.

Mr. Davies.

J. V. Davies, M. Am. Soc. C. E.—In working out the study of any individual case that is presented, the thing that particularly impresses the speaker more than anything else, is the great scope for the display of engineering ability in the various special lines of the Profession. In the last few years, in connection with the Interstate Bridge and Tunnel Commission, the speaker has discussed at public hearings the relative advantages of bridges or tunnels for vehicular traffic across the Hudson River to such an extent that the subject has become almost tiresome.

There are a great many marked advantages in certain particular cases in the use of tunnels for subaqueous highway purposes over the use and adaptation of the bridge: they are better protected; they present less external obstruction; there is less cost of maintenance, which is a very large item; and per track or per roadway, they will probably cost materially less. Another obvious advantage is that a bridge has to be constructed in the first instance for the full permanent use and purpose for which it is required; whereas, in the case of tunnels, single roadways can be constructed and added to as the volume of business extends, and such additional tunnels can be located and distributed as traffic requires.

It is certain that there will be a growing use of tunnels for highway purposes. The speaker, while in London recently, was rather interested in the fact that the Rotherhithe and Blackwall Tunnels

* This discussion (of the paper by George Duncan Snyder, M. Am. Soc. C. E., published in May, 1914, *Proceedings*, and presented at the meeting of September 16th, 1914) is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Davies.

had been closed entirely to traffic, due to the fear of war conditions, involving the use of bombs or explosives which might cause serious injury to those structures. Reference has been made to a pertinent question, arising from the conditions developed during the procedure of war in Europe, as to the destruction of bridges across rivers by the contending armies, and it is really a matter of thought, whether a tunnel in such cases—with the ability to flood it and render it temporarily useless without permanent injury—has not a very great advantage over a bridge for ordinary highway purposes.

On the question of the transporter bridge the speaker has studied very closely three of the largest of such bridges—those at Runcorn and Newport, in England, and the one at Rouen, France. At all these bridges there is considerable rise and fall of the tide. At Newport, particularly, the average rise and fall of the tide in the River Usk, where the bridge is located, is some 35 ft. When the water is at high level the river is a very fine and noble stream. At low water there is a mud valley with a small creek at the bottom of it. A ferry service is impossible. An ordinary highway bridge would be difficult and expensive to build, and even with draw-spans would be a serious interference to navigation. A tunnel, on the other hand, on account of the banks and river valley, would require such approaches as would render it undesirable for such purpose; and where the traffic is very small, as it is in this case, and as it is also in Rouen and Runcorn, there is no warrant for constructing any very large and expensive draw-bridge, or, on the other hand, any expensive tunnel, for such conditions; whereas, the transporter bridge, giving a fixed end landing and reasonably frequent service, at low initial cost, serves the purpose of transportation admirably. This is an illustration of the fact that each individual case must be considered on its own merits.

The greatest point of advantage in the use of a subaqueous tunnel, over any other method of conveyance for highway uses, is its flexibility of location. The Rotherhithe Tunnel does not go squarely across the river; even the approaches are at varying angles; and the location and design of the tunnel were evolved to connect two great populous districts which had business intercourse and business interests on each side of the Thames, where that intercourse was urgently necessary. The tunnel, therefore, was constructed on a zigzag alignment. Crossing the Thames on a diagonal line, it allowed communication to be had between districts that required that communication, and, to the speaker's mind, more than anything else, that flexibility of location for highway purposes is one of the most important features in the consideration of this subject.

EXTERNAL CORROSION OF CAST-IRON PIPE.

Discussion.*

By C. P. Bowie, Assoc. M. Am. Soc. C. E.

Mr. Bowie.

C. P. Bowie, Assoc. M. Am. Soc. C. E. (by letter).—The writer has read this paper with great interest. Although the author has dealt primarily with cast-iron pipe, some of the methods for the prevention of external corrosion would apply equally to steel pipes. In California a number of companies are operating 8 and 10-in. oil pipe lines which pass through many miles of semi-arid lands where the soils are strongly impregnated with alkali. The total salts in these soils may be said to range from 0.05 to 5%, the average composition of the alkali salts being about as follows:

Potassium sulphate	11.28%
Sodium sulphate	19.48%
Magnesium sulphate	2.89%
Sodium chloride	23.03%
Sodium carbonate	40.96%
Sodium phosphate	2.08%
Sodium nitrate	0.28%
	100.00%

Soil taken from the immediate vicinity of a pipe which had been in the ground for nearly 4 years and was badly pitted showed the following composition:

Sodium carbonate	0.02%
Sodium chloride	0.05%
Sodium sulphate	1.31%
Magnesium sulphate	0.14%

* This discussion (of the paper by Marshall R. Pugh, M. Am. Soc. C. E., published in August, 1914, *Proceedings*, and presented at the meeting of October 7th, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Bowie.

The pipe lines are of wrought steel, about $\frac{5}{16}$ in. in thickness, tested in the factory to withstand a working pressure of 1 200 lb. per sq. in., although in practice they are seldom subjected to pressures exceeding 800 lb. per sq. in., and general operating conditions call for an average working pressure, at the pumps, of about 600 lb. per sq. in.

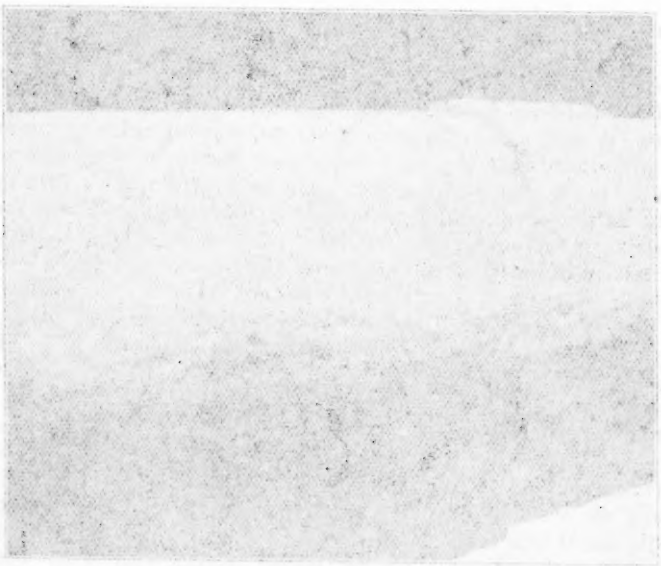
Instances are on record where such pipe, although originally protected with three coats of asphaltic paint, has corroded so badly in 3 years that the pit holes extended entirely through the metal. It is interesting to note that these pit holes often occur in portions of the pipe where the surrounding area shows little if any sign of corrosion. They are usually from $\frac{1}{2}$ to $\frac{3}{4}$ in. in diameter at the top, and often have the appearance of having been gouged out of the metal. Fig. 25 shows a number of such pittings in an 8-in. pipe which had been treated with two coats of asphaltic paint when laid, and had been in the ground a little more than 4 years. Fig. 26 shows a cast-iron saddle used for repairing pit holes which have developed into leaks.

Although in some cases adjoining property owners would have no objection if the pipe lines were carried on trestles above the surface of the ground, as Mr. Pugh states was done with the 48-in. pipe at Atlantic City, this method causes serious difficulty when it is considered that oil is pumped through these lines at temperatures (at the pumps) as high as 160° Fahr., and that insulation against the loss of this heat, such as is afforded by an earth covering of 2 ft. or more, is often essential to their successful operation, especially during the winter. Where the lines are placed on trestles of any extended length, the necessary insulation must be supplied, and this is expensive, even under the most favorable conditions. It is worthy of mention in passing that in places where a continuous length of a mile or more of pipe has been carried on trestles, across low swampy lands abounding in bulrush or tule growth, an almost ideal insulation has been effected by enclosing the line in a boxing of 2-in. plank, the space between the inner walls of the box and the pipe being stuffed with the dried tule.

In reference to the use of concrete as a protection: this method was tried a number of years ago by one of the large companies, but without success. The expansion and contraction of the pipe, caused by the high temperature of the oil and the relatively low temperature attained during the occasional necessary shut-downs, which allowed the pipe to cool to the temperature of the ground, soon cracked the concrete covering so badly that it was rendered practically useless. Moreover, collar leaks, which are of frequent occurrence in such lines, were not only difficult to repair, but as they necessitated the cutting away of the old concrete at such points, presented an even more serious defect, in that it was found practically impossible to

FIG. 25.—PIT HOLES IN 8-INCH STEEL PIPE, DEVELOPED IN A LITTLE MORE THAN FOUR YEARS.

FIG. 26.—CAST-IRON SADDLE USED TO STOP LEAKS DUE TO PIT HOLES.



put on patches of concrete without having cracks develop between the old and new material. Mr. Bowie.

A successful covering for such lines should be so elastic that it would expand and contract without rupture, in conformity with the pipe; it should afford insulation against loss of heat, and at the same time be impervious to the passage of water. Working along these lines, a number of coverings have been brought forward. Various kinds of asphaltum paint have been used, but, thus far, at least, without any marked degree of success. Crude oil has also been applied, by covering the pipe, after it has been lowered into the trench, to a depth of 6 in. or more with the oil, and then immediately filling in the trench with earth. This method is only partly successful, because, if the soil is at all sandy, the oil soaks into it and in time almost entirely disappears from the vicinity of the pipe, leaving the metal quite as badly exposed to the alkali as before the application. Quick-setting bituminous enamels, which can be put on in a layer from $\frac{1}{8}$ to $\frac{1}{4}$ in. thick, bid fair to give results. However, up to the present, these enamels have one serious drawback, in that they cannot be applied successfully to a moist pipe or to one having a temperature lower than 60° Fahr., because the enamel, although it is put on at a temperature of approximately 200° Fahr., is chilled so rapidly that it hardens before it can be spread. The action of the mop with which it is applied is merely to roll it into a myriad of balls or globules, which do not stick to the pipe but fall to the ground. This not only causes a great waste of material, but is apt to leave many small portions of the pipe, especially on the under side, wholly unprotected, even though several coats of enamel are put on. This difficulty, however, can be largely overcome by applying the enamel in warm dry weather only, or to pipes through which warm oil is being pumped. There are no lines in the State which have been covered by this process and allowed to remain in the ground for any great length of time. One line, passing through slightly alkaline territory, which was covered in this manner about 4 years ago, was found to be in excellent condition on recent examination.

The method of covering most extensively used, and perhaps the most successful one, is that utilizing specially prepared roofing papers. Those commonly used are made from ordinary deadening felt; they are run through a mill in which the felt is plunged into a number of successive baths of hot asphaltum and rolled hot and under pressure after each bath until the fibers of the paper are thoroughly impregnated with the asphaltum. Just before entering the last set of rolls, the paper is sprinkled with either mica or soapstone. These minerals, though no doubt adding somewhat to resistance against the attack of chemicals, have for their principal function the quality of keeping the paper from sticking in the roll in hot weather. Asbestos papers,

Mr. Bowie.

prepared in a manner somewhat similar, have also been used in a number of places. These papers are applied to the pipe by one of two methods known locally as the "spiral wrap" and the "longitudinal lap". The spiral wrap consists of applying the paper to the joints between collars by wrapping it around the pipe spirally. For this purpose, the paper is cut in the mill into rolls of the desired size, varying from 3 to 12 in. in width, and from 50 to 100 ft. in length, as best suits the diameter of pipe to be covered. The pipe is covered immediately after being screwed together by the tong gang, and while still on skids over the trench. It is coated with hot asphaltum, and the wider strips are wound on spirally before the asphaltum has had time to set. The crack which is left between each wrap of the wide strip is then coated with hot asphaltum, and a batten, or 3-in. strip, is wound on to cover it. The asphaltum is a thin grade of the ordinary refined product. It is applied to the pipe at a temperature of about 200° Fahr., and is of such consistency that it will not set for about 5 min. after application. If, due to climatic conditions or variation in the different shipments, the asphaltum sets too quickly, a so-called flux, which is simply a very thin grade of asphaltum, is added. It is usually the practice to ship 1 bbl. of flux to the field for every 60 bbl. of asphaltum. At the joints 3-in. strips stuck together with asphaltum are wound around the pipe on each side of the collar until a shoulder is built up flush with the outer circumference of the collar. The sleeve and shoulder thus built up are then coated with hot asphaltum, and the whole is covered with a 12-in. strip of paper. Besides being stuck to the pipe with asphaltum, this last strip is bound on with wire, as are also the ends of the paper where it is wrapped spirally. If this is not done, the ends will curl up and allow dirt to get between the paper and the pipe after the pipe has been lowered into the trench.

The longitudinal lap system, which, up to the present time, has been used much more extensively than the spiral wrap, consists (as the name implies) of wrapping the paper longitudinally around the pipe. The paper is delivered in the field in rolls, about 6 in. wider than the circumference of the pipe to be covered, each roll containing approximately 72 lin. ft. Two men go ahead of the paper gang and measure up each joint of pipe between collars and cut the paper into the desired lengths.

In applying the paper to the pipe undoubtedly the best method is first to coat the pipe with hot asphaltum, as previously described, then to wrap the sheet of paper around the pipe and stick down the lap with hot asphaltum. This, however, is not often done when covering lines where the oil passing through is to be heated, the supposition being that the heat of the oil (usually about 130° Fahr.), combined with the pressure of the earth on the pipe after it has been

buried, will be sufficient to soften whatever asphaltum there is in the paper and form the necessary bond between paper and pipe to keep the water out. Without question, this supposition is correct to a certain extent. The paper, especially where a heavy quality is used, will undoubtedly adhere to the pipe in most places where it comes in contact with the metal; but it is to be noted that roofing papers applied to a pipe, while the latter is still on skids above the ditch, and allowed to stand in the sun for a few hours, will stretch to such an extent that the contact will be found to be on the upper part only, there being often as much as ¼ in. of space between the bottom of the pipe and the paper. It is a serious question if this does not occur when the heat from the oil first reaches the paper, even though the pipe has been lowered into the trench and covered up. The paper, of course, does not bag uniformly, as in the case above ground, but the surplus is taken up in wrinkles, and these wrinkles are very apt to be connected for the entire length of a joint of pipe. Should an injury occur to one of these wrinkles or a crack develop in it, which will undoubtedly be the case as oxidation goes on, it is not at all improbable that water, which would enter, would reach every place in a joint of pipe where the paper was not securely stuck on, and thus render the whole covering practically useless. Where asphaltum is used as a binder, the wrinkles that form will be filled, thus preventing the water from entering, even though, in time, the paper should crack at these points. Time alone, however, can solve this much-mooted question, as there are no lines in California protected in this manner, which have been laid a sufficient length of time for these cracks to develop. Mr. Bowie.

For covering the collars, the same method is used as with the spiral wrap, except that the binder is often omitted. This, it would seem, is even more serious than omitting the binder from the main body of the pipe, as it gives the water a chance to get between the paper and the pipe through the ends of the wrinkles.

Whether or not a binder is used, the lap should always be made on the top of the pipe with the outer portion of the lap downward, and the wires should be placed about 16 in. apart. This is necessary in order to prevent the paper from being pulled away from the pipe by its own weight before it can be lowered into the ditch and covered.

A METHOD OF DETERMINING STORM-WATER RUN-OFF.

Discussion.*

By Messrs. R. C. Strachan and Kenneth Allen.

Mr. Strachan.

R. C. Strachan, M. Am. Soc. C. E.—The work of the author in gathering and sifting data for comparing the results obtained from numerous run-off formulas, and in epitomizing the influences of the many factors in a new formula taking into account soil conditions, grades, rainfall, density of population, and extent of territory drained, is one of great magnitude, and is of permanent value to the designing engineer, even though, in his judgment, the new formula may not be universally applicable.

Such a formula is necessarily far from simple, and its practical utility must depend largely on the diagram or other device by which ease and celerity of solution are promoted.

It cannot be said that simplicity is the dominant feature of the diagrams accompanying the paper; and it is unfortunate that Mr. Buerger did not make use of the nomographic method of charting, by which Plate XIV could be reduced to three lines and the diagrams for finding P and N constructed so as to eliminate absolutely the maze of intersections shown in Figs. 3 and 4.

Mr. Allen.

Kenneth Allen, M. Am. Soc. C. E. (by letter).—The effort to find a run-off formula, both easy of application and reliable, is one that should meet with approval. If we could only be in possession of all the factors affecting the phenomena of run-off, its determination by a rational formula would leave nothing to be desired, and it has been the writer's opinion for some time that where conditions of topography or

* This discussion (of the paper by Charles B. Buerger, M. Am. Soc. C. E., published in August, 1914. *Proceedings*, and presented at the meeting of October 7th, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

Mr. Allen.

climate vary to a material degree from those on which such empirical formulas as the Bürkli-Ziegler are based, it would not be safe to use any but the rational method. The great difficulty here lies in the fact that the data necessary for its proper application—such as maximum intensity of precipitation and time of concentration—are so rarely known; and, if they are to be guessed at, why not use some more convenient empirical formula?

The weak point in formulas of the Bürkli-Ziegler type lies in their failure to provide for differences in the time of concentration due to the shape of the drainage area. They all have the merit of easy application, but, as the author points out, they were (excepting the Gregory formula) developed from local data, and, therefore, were not necessarily applicable to other places.

In any case, lack of care in the selection of proper values for C and R may result in large errors. In particular, the value of R appears to be subject to different interpretations by different engineers. It is usually stated—as by the author—as "rainfall, in inches per hour," but it is frequently taken as the rate of precipitation, in inches per hour for 10, 20, or 30 min., or for the probable time of concentration for the area in question. If we determine the rate of precipitation by Formula (13) this, and consequently Formula (9), will be twice as great if $t =$ 20 min. as if $t = 60$ min. The importance of definite understanding on this point is evident. The value to be assigned to R or I depends on the long-continued records of a self-registering gauge on or near the drainage district.

The determination of R for the conditions of maximum run-off, or I, involves the time for concentration, which in turn depends on the hydraulics of the drainage vehicle, the shape of the area drained, and the distribution of the rain on this area. These present a difficult problem to be solved for each sewer district, if accuracy is attempted, and the results of rain-gauge observations and sewer gaugings for long periods are necessary for its solution. Those who have attempted it know the care necessary to determine the correct discharge of a sewer in times of storm, where surface levels vary without apparent cause and friction coefficients can only be known by special experiments. One factor, which applies to large areas, that is often overlooked, is the decrease in average maximum intensity as the area increases. This factor has been called a "distribution coefficient" by Messrs. Wynne-Roberts and Brockmann,* who propose a value expressed by the formula, $C = 1 - 0.002 \sqrt{L}$, in which L is the length, in feet, of the longest line of sewer above.

The author reduces all values of R to that for 60 min., which he calls K, and then deduces his empirical formula to conform as well as may be with the results of actual gaugings. Besides the merit of being

* *Canadian Engineer*, Vol. 24.

Mr. Allen.

definite, in this respect, there is the further advantage in the use of K, pointed out by the author, that there are many more records available for 1 hour than for shorter periods.

Whether the relation of the maximum hourly rate to that for the shorter periods on which the capacity of sewers is usually based is constant for different locations seems to be improbable, and, for this reason, a formula using the shorter period, or one based on the time for concentration, would appear preferable.

One difficulty has been met in determining high rates of precipitation for short intervals with most of the recording gauges in use due to the necessarily small scale of hours ($\frac{1}{2}$ in. or less per hour). This has been ingeniously overcome by George A. Carpenter, M. Am. Soc. C. E., by causing a jar to be given to an arm carrying the recording pen every 5 min. by the clock mechanism. This produces a short horizontal line across the line on the chart which, at such times, approximates the vertical, and the precipitation for any 5-min. interval can then be scaled off quite correctly between any two consecutive horizontal lines.

The selection of K, or the frequency with which surcharge of sewers may be allowed, is an important and delicate matter, involving undue cost of construction on the one hand and the possibility of loss and consequent damage suits from flooding basements on the other. The assumption of a value of K corresponding to 12 months suggested by Dr. Imhoff as reasonable is, in the writer's opinion, far too short a period for well-developed conditions in large cities, where 10 years or more would often be warranted.
